\section*{ABSTRACT}

Degradation kinetics and the thermal stability of Invar 36 powder injection moulding feedstocks (PIM) based on cellulose acetate butyrate (CAB) and polyethylene glycol (PEG) binders were investigated using simultaneous thermogravimetric analysis (STA) and differential scanning calorimetry (DSC). The initial decomposition temperature (IDT) and the integral procedure decomposition temperature (IPDT) were used to analyse the thermal stability of the binder system as a function of the solid loading content and powder particle size. The degradation kinetics was studied, and the process apparent activation energies were assessed using isoconversional methods. All the methodologies revealed changes in the thermal degradation behaviours of the feedstocks for solid loadings that were previously determined to correspond to optimal solid loadings using other experimental procedures. The studies also contrast previous similar findings with a ceramic powder. Therefore these results strengthen the proposal of thermodynamic degradation studies of feedstocks as an alternative or complementary technique to determine optimal solid loading contents in metal injection moulding (MIM).

\section*{1. Introduction}

Powder injection moulding (PIM) is one of the main manufacturing processes used to produce small parts with complex geometries, thin walls and in large production batches [1]. This technology is applied to a wide variety of ceramics (commonly referred as ceramic injection moulding, CIM), metals (also referred as metal injection moulding, MIM) and combinations thereof [2]. The process consists of mixing a fine powder material with different polymer like compounds, the so called binder system. The binder system provides sufficient fluidity to the newly created feedstock to allow mould filling during injection. However, it will be removed during the subsequent debinding process, thus it has to allow an easy extraction. The binder system must be added in such quantities so as to optimise the process conditions and time required.

Elimination of the binder system out of the green body is the bottle neck in MIM processes and a critical and delicate step. It requires tailored optimisation of the time–temperature cycle in order to be economical and effective while avoiding faults like undesirable blistering [3]. For multi component binders obtaining optimal thermal cycles is a difficult task that conventionally has been performed by “trial and error”. However recent works propose to investigate the binder decomposition kinetics in order to identify points of rapid weight loss to avoid green parts damage, to speed up the debinding process and lower the overall cost [4–6].

The thermal burn out of organic components during debinding processes of MIM feedstock is intricate. There are several decomposition mechanism involved which are also dependant on several factors. Transport and elementary reactions steps could be rate limiting during debinding. Transport mechanisms would become more influential with increasing sample thickness, whereas in thin specimens such as in micro pieces, polymer decomposition kinetics would play a predominant role [7].

In previous works [8] we have proposed thermogravimetric analysis as an alternative to determine optimal solid loading for ceramic feedstocks while studying their thermal stability and decomposition kinetics. In this work same methods are contrasted with metallic powders. Calorimetric and thermogravimetric analyses were performed to study the thermal decomposition of an Invar 36 alloy (Fe\textsubscript{0.64}Ni\textsubscript{0.36}) feedstocks composed of cellulose acetate butyrate (CAB) and polyethylene glycol (PEG) binders in an...
inert nitrogen atmosphere. Binder and feedstock temperature stability and decomposition kinetics were investigated using integral procedure decomposition temperature (IPDT) and isoconversional methodologies, respectively. A number of isoconversional methods were used, and their convenience discussed.

Several Invar 36 feedstocks consisting of mixtures with different proportions of constituents were investigated. The volume fractions of metallic powders as well as the powder particle sizes were varied in this study. These variations allowed the effect of the effective powder surface on the interactions of CAB and PEG mol ecules with Invar 36 particles and the channel volume used to remove volatiles to be elucidated. The degradation of the binder system was studied to evaluate the extent of the influence that particles exert on the decomposition of CAB and PEG. The results reveal changes in the thermal degradation behaviour with solid loading and particle size. Based on these findings, we have con trasted the suitability to determine the optimum solid loading conditions using thermogravimetric tools.

2. Thermal stability studies

The initial decomposition temperature (IDT) and the integral procedure decomposition temperature (IPDT) were used to analyse the thermal stability of the binder system as a function of the solid loading content and particle size. The IDT indicates the apparent thermal stability of binder system with regard to the maximum feedstock processing rate and moulding temperatures. The IDT is determined by the onset weight loss in the TGA curves of the different feedstocks. In this work IDT corresponds to the temperature at which the 2% in mass of the organic compounds was lost. The IPDT determined from the residual weight fraction in the TGA is a reproducible datum that can be consistently determined for diverse materials and represents both a truly comprehensive index of intrinsic thermal stability and a real temperature that has practical significance. The method for calculating the IPDT is proposed by Doyle [9,10] and converts the area under the TGA curve into a value that approximately represents the characteristic end of volatilisation temperature, T* (Eq. (1)):

\[ T_\text{IPDT} = A^* \cdot \left( T_\text{f} - T_\text{i} \right) + T_\text{i}, \tag{1} \]

where \( A^* \) is the area under the TGA curve within the evaluated temperature range (defined by initial temperature \( T_\text{i} \) and the final temperature \( T_\text{f} \)) and normalised with respect to both the residual weight and temperature. However, the IPDT takes into account the amount of refractory or non volatile residues at \( T_\text{f} \) by means of the coefficient \( K^* \). Therefore, the method to calculate the IPDT is described in Eq. (2):

\[ \text{IPDT} = A^* \cdot K^* \cdot \left( T_\text{f} - T_\text{i} \right) + T_\text{i}, \tag{2} \]

A representation of the areas \( S_1, S_2 \) and \( S_3 \) used to calculate \( A^* \cdot \left( S_1 + S_2 \right) / \left( S_1 + S_2 + S_3 \right) \) and \( K^* \cdot \left( S_1 + S_2 \right) / S_1 \) is shown in Fig. 1. In these cases, the IPDT represents the inherent thermal stability of the binder system and describes the entire binder degradation process in terms of the decomposition and vapor isation of the different volatiles taking into account differences in the solid loading percentages. The higher the IPDT is, the more thermally stable the feedstock is. Thus, the binder components will resist higher temperatures until complete volatilisation occurs.

From the IPDT definition, it is clear that this value will be influenced by the selection of initial and final temperatures. To the best of the authors knowledge there is not a standard that defines where to set these temperatures. Hence, there is a limitation of using IPDT value when different systems are compared. In this work initial temperature was selected approximately considering the 20% below the IDT, which resulted to be 50 °C. For the final temperature, approximately the 20% above the end of degradation temperature was selected, which resulted to be 600 °C. For comparative purposes this limits were maintained when determining the IPDT of different feedstocks and binder system components.

3. Degradation kinetic studies

A thorough discussion about the convenience of using model free isoconversional methods to analyse thermal decomposition of MIM feedstocks could be found in the work of Salehi et al. [7]. Model free methods turn out to be the most reliable way to determine kinetic parameters of thermally activated complex processes, because the prior knowledge of the reaction mechanism is not necessary [11]. These methods are based on studying the degree of conversion with respect to temperature at different heating rates. The degree of conversion for a certain temperature \( \alpha \) is defined as the ratio of the actual weight loss \( m(T) \) to the total weight loss, as expressed in Eq. (3):

\[ \alpha(T) = \frac{m(T)}{m_0}. \tag{3} \]

The variables \( m_0 \) and \( m_\infty \) correspond to the initial and final masses, respectively. In the model free methods apparent activation energy is calculated directly from the TGA curves. The term apparent activation energy comes for the uncertainty of the physical process associated to this activation energy. Activation energy most likely takes into account several different processes occurring at the same time. The rate of degradation, \( da/dt \), is assumed to depend on the temperature and weight of the sample. Therefore, the main advantage of eliminating the necessity of a kinetic model is clouded by the influence of the sample mass and size in the apparent kinetics parameters calculated. Furthermore these parameters could be influenced by the thermal lag across the specimen [12]. To reduce possible errors regarding size and mass, samples of similar dimensions and masses were employed. It is assumed for the thin disks employed that the binder removal rate is predominantly determined by decomposition rates of organics and not by transport processes.

In literature a wide variety of non isothermal models could be found. The lack of agreement among kinetic parameters calculated from the same set of experimental data using different methods of mathematical analysis is disturbing. It has been shown that the causes for these differences are due to the intrinsic nature of the methods. In this work Flynn–Wall–Ozawa (FWO) and Kissinger–
Akahira–Sunose (KAS) integral methods are selected to estimate apparent activation energy values. They are based in the integral of the following expression (Eq. (4)):

$$\frac{d\alpha}{f(\alpha)} = \left(\frac{k_0 \cdot \exp\left(\frac{E_a}{R \cdot T}\right)}{\beta}\right) \cdot dT,$$

(4)

where $k_0$ represents the pre exponential factor, or frequency factor; $E_a$ is the apparent activation energy; $R$ is the gas constant; $T$ is the absolute temperature; and $\beta$ is the heating rate ($dT/dt$).

The FWO [13,14] method is based on the principle that a reaction rate at a constant conversion is only a function of temperature. Using Doyle’s approximation [15] of the temperature integral $p(E_a/R \cdot T)$ and applying logarithms, the following expression is produced (Eq. (5)):

$$\log(\beta_i) = \log\left(\frac{k_0 \cdot E_a}{R \cdot g(\alpha)}\right) + 2.315 \cdot 0.4567 \cdot \left(\frac{E_a}{R \cdot T_a}\right),$$

(5)

where $g(\alpha)$ represents the integral of $d\alpha f(\alpha)$. Considering a constant conversion, the representation of $\log(\beta_i)$ vs. $1/T$ should be a straight line with a slope defined as $d(\log(\beta_i))/(d(1/T)) = 0.4567/E_a/R \cdot T_a$. Therefore, the activation energy may be calculated from Eq. (6) as follows:

$$E_a \quad \text{slope} = \frac{R}{0.457}.$$

(6)

The KAS method [16,17] (Eq. (7)) is based on the Coats–Redfern [18] approximation of the temperature integral $p(E_a/R \cdot T)$ and considering that $2 \cdot R \cdot T_a/E_a$ is much less than unity. The resulting relationships are expressed as:

$$\ln\left(\frac{\beta_i}{T_a^2}\right) = \ln\left(\frac{k_0 \cdot R}{E_a \cdot g(\alpha)}\right) - \frac{E_a}{R \cdot T_a}.$$

(7)

Thus, the plot of $\ln(\beta_i)/T^2$ vs. $1/T^2$ for constant values of $\alpha$ and $zi$ should be a straight line with a slope that can be used to calculate the apparent activation energy (Eq. (8)):

$$E_a \quad \text{slope} \cdot R. $$

(8)

Some of the main shortcomings of both methods are using an approximation of the temperature integral and the selection of the integral limits, but the validity of the calculated apparent activation energies is assumed good enough for the general proposes of this work.

4. Experimental procedure

4.1. Materials

Gas atomised spherical Invar 36 powders were supplied by Sandvik Osprey Ltd., (UK). Two powders with different particle sizes were selected in this study. The coarsest powder was denoted as INV1 whereas the finest powder was denoted as INV2. A Malvern 2000 laser scattering device was used to measure the particle size distribution parameters. The powders specific surface areas were measured with a Micrometrics Gemini VII BET measurement device. All the particles parameters for both INV1 and INV2 are collected in Table 1.

A binder system based on PEG and CAB was selected. These binders have been demonstrated to be effective for PIM and provide improved properties when compared to other binder systems [19,20]. However, there are no published comprehensive studies on their thermal degradation when Invar 36 particles are added. The binders consist of two types of CAB: CAB381 0.1 and CAB551 0.01 (Eastman). Each of these binder components has different per centages of butyryl, acetyl and hydroxyl groups. They were blended with two types of PEG (Sigma Aldrich) with different average molecular weights. The composition of the binder system and the characteristics of the components are shown in Table 2.

4.2. Preparation of the samples

A Rheomix 600 Haake rheometer coupled with a Haake Rheo cord 252p module was used for the mixing all feedstock compo nents. Different feedstock compositions, ranging from 57.5 vol.% (minimum solid loading tested) to 72.5 vol.% (maximum solid loading tested), were investigated in 2.5 vol.% increments. A tem perature of 150 °C was used for all the batches, and the mixing chamber was filled with feedstock to 72% of the total volume (the chamber volume is 69 cm$^3$). A rotor speed of 50 rpm was employed to mix the feedstock and the binder for 60 min to ensure complete homogenisation. Thin samples of around the same size and weight were prepared by warm pressing of the as prepared feedstocks to perform thermogravimetric and calorimetric analysis.

4.3. Thermogravimetric and calorimetric analyses (STA and DSC)

A Perkin Elmer STA 6000 device was used to thermodynamically evaluate the decomposition of the binder and the feedstock. This device allows the simultaneous acquisition of the thermogravi metric TGA curves and the DTA/DSC curves. The examined tem perature range was from 50 °C to 650 °C. Calcium oxalate was employed for thermogravimetric calibration, whereas elemental indium (99.999% pure) was used for heat and temperature cali bration. An inert nitrogen atmosphere was employed with a flow rate of 40 ml/min. Feedstock pellets of approximately the same morphology and weight were used for the analysis. The net weight of the binder in the feedstock was constant for all experiments, with a minimum of 5 mg for all cases. An open aluminium oxide crucible was used to perform the experiments. For a thorough evaluation of the decomposition kinetics, four heating rates were evaluated: 10 °C/min, 15 °C/min, 20 °C/min and 25 °C/min. The buoyancy effect in TGA has been taken into account by carrying out empty crucible runs and subtracting the resulting weight differ ences from the subsequent sample mass loss data [21].

A TA Instruments Q200 differential scanning calorimeter (DSC) equipped with a refrigerated cooling system was also employed to contrast STA results. The base line was calibrated in scanning the temperature domain with an empty pan. The temperature and the enthalpy were calibrated using indium as a standard. All the

experiments were carried out with an aluminium pan with 8–12 mg of sample. These experiments allow data acquisition at lower temperatures ranges with a better resolution than with combined STA technique. Typical heating–cooling–heating cycles were programmed to delete the thermal history of the feedstocks and to evaluate the melting and crystallisation temperatures. The experimental temperature range varies from 20–190 °C to avoid any possible degradation of the components and to allow complete crystallisation. Heating rates of 10 °C/min were selected.

4.4. Polarised light microscopy

Investigation of PEG crystallisation in different systems was performed by an Olympus GX71 light microscope with light polarising filters. A thin layer on around 0.5 mm was created by facing two microscope slides and pressing the sample in its melting state. Samples were melted at 160 °C during 30 min. Then they were air quenched at same cooling rates for comparison purposes.

5. Results and discussion

5.1. DSC investigations

Characteristic melting and crystallisation PEG peaks as well as CAB transition temperatures were investigated by DSC measurements. This study was done for the single binder components, the binder and the different feedstocks. Changes in the peaks features in terms of temperature displacements and specific enthalpies increment may reveal the occurrence of interactions between binder components and between binder components and powder particles. These interactions may affect the decomposition behaviour of the feedstocks. Salehi et al. [7] demonstrated that the kneading effect and the presence of powder particles in PS promote the formation of weak links between polymer chains. This was related with a lowering of the degradation activation energy which enables the weak links to act as initiation points for PS degradation.

In Fig. 2 the DSC curves of the binder system and the binder components are plotted. Table 3 collects characteristic events during the heating and cooling processes of the single binder components. The melting and crystallisation peaks associated to the PEG components and the binder system. $T_{mPEG}$: PEG melting temperatures; $T_{cPEG}$: PEG crystallisation temperatures; $T_{gCAB}$: glass transition of CAB; $\Delta H_{mPEG}$: specific enthalpy of melting relative to the PEG mass; $\Delta H_{cPEG}$: specific enthalpy of crystallisation relative to the PEG mass.

Comparing different binder components and binder system, differences in the melting and crystallising of PEG10k and PEG20k are comprehensible due to the differences in their molecular weights. Differences in the glass transitions of the CAB are also predictable due to differences in the side groups’ composition. The PEG20k and PEG10k melting points are very similar in contrast with the differences observed in their crystallisation peaks. The melting point is less sensitive to variations of the molecular weight but this feature or others affect on the crystallisation kinetics of the PEGs. A melt behaviour of the CABs, differences in the crystallisation peaks, were observed by controlled temperature polarised light microscopy experiments during cooling. The PEG20k began to crystallise at higher temperatures and a higher density of nucleation points was observed. Contrary, the PEG10k began to crystallise at lower temperatures and less nucleating points were observed. These results are consistent with the DSC measurements. As result big spherulites are observed for PEG10k compared with those for PEG20k as shown in the POM images presented in Fig. 3.

The melting and crystallisation peaks associated to the PEG components in the binder system fell drastically to temperatures far below those of the single components, however, the enthalpy related to PEG mass increased. These facts can be explained by a certain miscibility of CAB and PEG polymer chains, which is supported by two observations: a) Both CAB381 and CAB551 presented a glass transition which was not detected in the binder system; b) The increase of melting enthalpy related to PEG mass suggests that CAB takes part in the formation of PEG crystals. It would be explained by a widening of glass transition temperature range for the CABs and a displacement of this glass transition to lower temperatures. This would be agreed with and strengthen the assumption of the interactions between the CABs and PEGs binder components. In addition to DSC measurements, controlled temperature polarised light microscopy experiments during cooling were carried out. Onset of crystallisation of PEG spherulites in the binder system occurred at lower temperatures than those for single PEGs which is coherent with DSC results. However a higher density of nucleation points were observed compared with single PEGs. This also emphasises interactions between components; the CABs molecules most likely act as a nucleation agent but also retard the crystallisation during cooling. A polarised optical microscope (POM) image of the binder system is shown in Fig. 4. A decrease of the spherulites size in comparison with Fig. 3a–b, which represents the single PEGs, could be observed. This image also shows a zone that presents a variation in the spherulite morphology. The spherulites borders are blurred most likely as consequence of high concentration of CAB and certain interactions between both substances.

Fig. 2. Normalised heat flow vs. temperature DSC curves for the binder system and the single binder components.

Table 4 shows the influence of the solid loading and particle size on the melting and crystallisation peaks associated with the PEGs. One remarkable finding is the general observation of these peaks at temperatures between those for the PEGs and the binder system. A reasonable explanation of this fact could be given considering interactions between the binder components and the metallic
powders. Most probably PEG chains interact with the powder which is evidenced by the feedstocks PEGs' peak displacement to higher temperatures than the PEGs' peak corresponding to the binder system. Invar 36 particle surfaces are covered by a natural occurring oxide layer. Namely, hydroxyl groups are well reported to be present on metal oxide surfaces [22]. Several works studied the interactions between PEG and silica or alumina powders by infrared spectroscopy [23,24]. They state that hydrogen bonds are formed between the PEG etheric oxygen group and the metal surface hydroxyl group. PEGs' chains, if thermally or mechanically driven, may possibly have a higher interaction with oxide surface. In the same way, CABS interactions with metallic powders are not discarded but they could not be proven, neither experimentally nor by literature. Further studies should be carried out to ascertain the nature of possible bondings.

The melting and crystallisation temperatures are not very influenced by the solid loading up to certain points that depend on the particle size. In INV1 feedstock a pronounced melting and crystallisation temperature fall occurs at 70 vol.% solid loading whereas the similar behaviour is observed for INV2 at 65 vol.% solid loadings. These compositions were associated with critical powder volume content (CPVC) situations in previous studies. The enthalpy values also show similar behaviours but the drop on the enthalpy values occurred at 60 vol.% in the case of INV2. As long as there is enough inter particle gap to allow the formation of PEG's crystal line regions, the phase transitions will not be critically altered. In such cases the effect of high free volume for crystallisation prevails over the effect of the particle surface increment and reduction of inter particle distances. Since the particles packing is increased, the confinement of the organics is increased reducing the effective volumes that will allow a free growth of crystalline lamellas. Comparing both powder types, there is a significant crystallisation temperature reduction in case of INV2 feedstock while these variations are less obvious but also occurs with the melting points.

5.2. Thermal stability studies

Fig. 7a shows typical simultaneous thermal analysis curves for Invar 36 feedstocks: in this case curves for an INV2 feedstock with 60 vol.% and a heating rate of 10 °C/min are plotted. The normalised DSC curve can be plotted simultaneously with the TGA curve and its derivative, the DTG curve (or the weight loss ratio). Fig. 7b focuses on a comparative of the TGA curves between INV2 feedstocks with different solid fractions. Similar tendencies are observed for INV1 feedstocks.

Table 5 collects some decomposition parameters at 10 °C/min of the different feedstock compositions and Table 6 does for the binder and the binder's components. The initial decomposition temperature (IDT) represents the temperature at which the 2 mass % of the total binder mass was eliminated. The T_{max} and the \Delta H_{\text{Int}} represent respectively the conversion and temperature at the maximum weight loss ratio point. The T_0 represents the extrapolated temperature at the maximum weight loss ratio considering a 0 °C/min heating rate. The Res refers to the organic residual mass at 600 °C pondersed to the total binder weight and the IPDT to the integral procedure decomposition temperature.

The feedstock organic components decomposition in nitrogen atmosphere occurs in three consecutive overlapped steps as it is deduced from feedstocks DTG curves (Fig. 7a and Fig. 5a–b). The highest decomposition rates occur at high temperatures and correspond to the volatilisations of compounds resulting from the

![Fig. 4. POM image of the binder system: i) zone with blurred PEG spherulites most likely as consequence of high concentration of CAB and certain interactions between both substances, ii) More common PEG spherulite typology most likely with less or no content of CAB.](image)
degradation of PEG which is the principal component of the binder. The two previous decomposition steps could be linked with the decomposition of CAB. The feedstocks' decomposition behaviour contrasts with a two step binder decomposition process as could be seen in the DTG curves for the single components and the binder system in Fig. 6. The first step occurring in the feedstocks' DTG curves is not registered in the decomposition of the binder system (Fig. 6). The idea that the first decomposition step occurring at low temperatures is associated with an interactive or catalytic effect of the powders over the polymeric compounds is not discarded.

The PEG seems to have a stabilising effect in the decomposition of the CAB as deduced from the displaced DTG peak associated with the CAB in the binder system to higher temperatures. This effect could be revealing some interactions between the CAB and the PEG which is in consonance with DSC results. Furthermore CABs and PEGs decomposition peaks tend to overlap in the feedstocks DTG curves. Although certain compatibility is assumed between CABs and PEGs, their miscibility is not complete as it was contrasted with well differentiated CAB rich and PEG rich regions in the binder system (Fig. 4). The kneading effect that the powder particles exerts over the binder components may cause a smaller and closer PEG rich and CAB rich regions or increase the miscibility between the molecules in case there is any. The CAB and PEG polymer chains may be more effectively entangled and the formation of weak links could be promoted. This would explain the displacement and overlapping of these substances decomposition peaks, presumably because of a hindering of the elimination of the CABs' decomposition components entrapped in these smaller domains.

The IDT of the binder system coincides with the minimum IDT of its components that corresponds to CAB551. However, there is a considerable reduction of the IDT values registered in the feedstocks and there is a clear dependence on the powder type and the solid loading. The lowest IDT values correspond to the INV2 feedstocks with high solid loadings. There is a direct relation of the total powder surface area with the IDT value. The main idea is that the mixing process favours the creation of weak links between polymers or between polymers and particles. These weak links are preferential points for the polymer chain scission during thermal degradation. It is well established that PEG thermal degradation proceeds by the random chain scission of C–O bonds [25]. Thermally promoted hydrogen abstraction reactions of hydroxyl radicals with C–O is one possible mechanism of chain scission. This reaction is kinetically more favourable than the own homolytic cleavage of C–O [26]. As the solid fraction increases or the powder particle size is reduced, there is more available surface area for the creation of hydrogen bond or weak links favouring a subsequent catalytic effect at higher temperatures.

The CABs do not completely volatilise at 600 °C in nitrogen atmosphere and leave a solid organic residue. The proportion of this organic residue with respect to the total binder is reduced in INV1 feedstocks in comparison with the INV2 feedstocks and the sole binder, both having similar values. As the solid loading increases, the residue increases. Although the powder surface may be having a catalytic effect on the polymers decomposition, it could be also a site for the formation of a thermally stable char layer. As the powder surface increases there are more sites for a char layer formation. There is also the effect of the powder particle packing increment over the binder components that corresponds to CAB551. However, there is a considerable reduction of the IDT values registered in the feedstocks and there is a clear dependence on the powder type and the solid loading. The lowest IDT values correspond to the INV2 feedstocks with high solid loadings. There is a direct relation of the total powder surface area with the IDT value. The main idea is that the mixing process favours the creation of weak links between polymers or between polymers and particles. These weak links are preferential points for the polymer chain scission during thermal degradation. It is well established that PEG thermal degradation proceeds by the random chain scission of C–O bonds [25]. Thermally promoted hydrogen abstraction reactions of hydroxyl radicals with C–O is one possible mechanism of chain scission. This reaction is kinetically more favourable than the own homolytic cleavage of C–O [26]. As the solid fraction increases or the powder particle size is reduced, there is more available surface area for the creation of hydrogen bond or weak links favouring a subsequent catalytic effect at higher temperatures.
This change in the slope may be explained assuming that the amorphous layer of the reaction products between the powder particles. The optimal solid loading is very near to the CVC with the difference that in the first situation there is still a thin coating of polymers embedding the particles. This coating layer is reduced for low solid fractions, despite a char layer formation is most likely taking place, there could be still enough separation between particles to allow an effective removal of all the decomposition volatile species out of the green body. Nevertheless, at optimal solid loading compositions the char layers of neighboring particles would collide hindering the volatiles evacuation causing the slope change. This slope change is telling that for subsequent solid loading in cements the variation of the $S_2$ areas is approximately constant while the values of the $S_1$ areas vary more abruptly (due to a reduction of the weight loss ratio and a displacement of the TGA curves to higher temperatures).

### 5.3. Degradation kinetics

The KAS and FWO methods allow determining the activation energy at different conversion values. Fig. 9 shows the dependence on the conversion of the apparent activation energy values, as assessed by the KAS method of the main binder components and the binder system while Fig. 10 does it for the INV1 and INV2 feedstocks at different solid volumetric fractions. Similarities are found in the curves using the FWO method thus this graph was obviated. The KAS method uses a more accurate approximation of the integral temperature than FWO and it is considered to produce more reliable results of the activation energy [21].

The activation energies for the PEG20k maintain approximately constant with $\alpha$ variations, which likely indicates a single rate limiting decomposition step over the entire reaction duration. The averaged value of $E_a$ using FWO method was 148 kJ/mol and in case of KAS method 144 kJ/mol. They properly suit with the typical PEG activation energies interval [120–200 kJ/mol] reported in literature [25]. In the case of CAB there is a slight increment of the activation energy with $\alpha$ from 57 kJ/mol for $\alpha$ = 0.2–0.7% to 59 kJ/mol for $\alpha$ 0.8 as determined with FWO and from 50 kJ/mol for $\alpha$ = 0.2–0.91% to 51 kJ/mol for $\alpha$ 0.8 as determined with KAS. Increasing dependence of the activation energy on the conversion is not unusual in polymer degradation [27]. This behaviour is considered to be an indicator of a complex reaction [28]. Vyazovkin and Lesnikovich [29,30] noted

Fig. 8. IPDT values evolution at different solid loadings, heating rates and for INV1 and INV2 feedstocks.
that in non isothermal experiments, patterns in the shape of the curve dependence of the apparent value of $E_a$ on $\alpha$ could provide insight into the type of complex process taking place. An increasing dependence of $E_a$ on $\alpha$ characterises concurrent, competitive reactions, whereas convexity indicates a change in the rate determining step. In the case of the binder system, the activation energies are higher than those for the single PEG and CAB. Several stages are observed. From conversion 0.2 to 0.4 a stable value of the $E_a$, with an average value of 172 kJ/mol calculated with FWO and 170 kJ/mol in case of KAS, is observed. Then $E_a$ increase up to 195 kJ/mol calculated with FWO and 194 kJ/mol in case of KAS for $\alpha$ 0.7. These results could agree with the suggested interactions between PEG and CAB observed by DSC. Grafting or cross linking reactions between CAB and PEG functional groups presumably occurs creating more thermally stable reaction nucleus and thus increasing the activation energy. It is not the scope of this work to study the nature of those reactions which would be also very limited by the employed techniques.

Through $\alpha$, the feedstocks seem to have an important influence on $E_a$ that is independent of solid loading. Two stages are mainly observed. For the majority of the curve, $E_a$ increases abruptly as the values of $\alpha$ increase up to a value at which $E_a$ either stabilises or begins to decrease; this behaviour gives the curve a certain convexity. At low conversion rates the activation energy is lower than those for the single PEG and CAB either stabilises or begins to decrease; this behaviour gives the curve a certain convexity. The concurrent reactions presumed from the $E_a$ increment could be molecular degradation reactions of both CAB and PEG and other reactions that hinder the volatiles evacuation as well as the formation of a thermally stable layer around the particles (by recombination of degraded polymers forming crosslinks or for mation of a char layer). The nature of this thermally stable layer and the reactions involving it are uncertain, but its formation is supported by the observation of an organic residue after TGA experiments. This residue is also observed in the thermal degradation of the studied CABs in nitrogen atmosphere. The subsequent plateau at high conversion values may indicate the end of a reaction or the creation of open pathways that facilitate the removal of volatiles as the binder decomposes. That last would suit with a slight pro gressive decrease of the activation energy at high temperatures. In many of the feedstocks, the value of the $E_a$ in the plateau at high conversion rates is higher than 195 kJ/mol (KAS), which is higher activation energy than those for the binder. This evidences that the presence of the powder influences negatively in the volatilisation of the break down molecules at high conversion rates.

Fig. 9. Evolution of the activation energies with the conversion calculated with the KAS method for the main binder components and for the own binder system. Fig. 10. Evolution of the activation energies with the conversion calculated with the KAS method at different solids loading for a) INV1 feedstocks and b) INV2 feedstocks. Fig. 11 represents the activation energies for a constant con version of 0.5 and for different INV1 and INV2 feedstocks using KAS and FWO methods. In this case a minimum in the activation energy vs. the solid loading curves is observed at 62.5 vol.% and 70 vol.% for INV2 and INV1 respectively. It is worth to consider that the apparent activation energy summarises different effects involving the degradation of polymers, but at the end, as measured from TGA, $E_a$ reflects how effective are the resulting break down compounds volatilised. Degradation may begin at temperatures lower than the registered by TGA. However, a weight loss only would be appreciated when the decomposition species had a certain low molecular weight that allows for the volatilisation or for the mass transport trough different mediums, e.g. melted polymer, evacuating inter particle pathways, etc. In that respect, the occurrence of a minimum in the $E_a$ vs. solid loading curve may be explained by opposing effects. First, an increment of the weak links as the solid loading increases, i.e. an increment of catalytic decomposition sites, may reduce the apparent degradations activation energy by favouring the fragmentation rate of the polymer chains. The opposite effect, an increase in the apparent activation energy, would occur as a consequence of a better particle packing as the solid loading increases, reducing the diameters of the volatiles removal channels. This effect may have been enhanced by the formation of a thermally stable layer of char around the particles. All of these effects combine to minimise the apparent activation energy of degradation.

Unfortunately non isothermal methods without other Supporting information have generally a no mechanistic value, but at least in this case could serve as a first rough approach to support the general analysis in combination with other methodologies presented. The KAS and FWO methods may introduce errors because they are based on an approximation of the temperature.
integral [15, 18], but in any case it seems that the results are reaf
firming 62.5 vol.% or 67.5 vol.% as the optimum solid loading value
with respect to both rheological concerns and thermal stability
studies of the feedstocks. The direct relationship between
the apparent activation energies, with respect to both rheological
and thermal degradation concerns, is not clear. There are analogies
in the possible explanations of the mechanisms that affect these fac-
tors, such as the change of the particle packing and the effective
interaction surface between the organic compounds and the par-
ticles. Nevertheless, studying the thermal degradation by calcu-
lat ing activation energies for different solid loading conditions
emerges as an alternative to the traditional rheological studies used
to assess optimal solid loading in PIM feedstocks.

6. Conclusions

Thermal analyses via DSC and TG experiments in a nitrogen
atmosphere were performed for different solid loading Invar 36
feedstocks composed of CAB and PEG. Two different powders sizes
were selected. Binder components in presence of powder particles
apparently thermally degrade by concurrent reactions in three
steps between 250 °C and 450 °C. A possible interaction between
the Invar 36 particles and the binder components was revealed by
DSC analysis. Thermal stability studies using the IPDT factor reveal
a linear slope in the feedstock thermal stability as the solid loading
increases. A change in the linear slope occurs at approximately
62.5 vol.% solid loading for fine powder whereas this change occurs
at 67.5 vol.% for the coarse powders. This change coincides with the
optimal solid loading calculated in previous studies using rheo-
logical methods. The kinetics of the thermal degradation of the
binder components in terms of calculated apparent activations
energies were also studied using the FWO and KAS integral
methods. Variations in the apparent activation energies calculated
using these methods suggest the occurrence of complex, concur-
rent and competitive reactions. A representation of the apparent
activation energy at a constant conversion for different solid loadings
shows that the activation energy is minimised at 62.5 vol.%
and 70 vol.% for fine and coarse powders respectively. This value
coincides with a minimum in the activation energy calculated using
rheological methods in previous studies. The possible effects that
lead on this minimum were discussed. It seems that the powder has
a catalytic effect upon the binder decomposition but at the same
time particles may be hindering the evacuation of volatiles. All of
these results emphasise the potential for using thermocalorimetric
analysis instead of, or as a complement to, conventional rheological
studies to determine the optimal solid loading of MIM feedstocks.
