February 11, 2014

## Abstract

Belarus experienced rapid economic growth in the 2000's, which abruptly came to halt after 2008. The authors found that the major source of growth was capital accumulation, while growth in total factor productivity (TFP) was modest. Moreover, government interventions and controls on the capital market contributed to misallocation which lowered aggregate productivity. Lack of productivity growth led to the loss of competitiveness on the international markets. Comparisons of TFP in Belarus with the Czech Republic and Sweden shows that comparative advantages of Belarus are concentrated in the natural-resource based industries, and TFP gap with the Czech Republic is not closing over time.

**Keywords:** Growth Accounting, Aggregate Productivity, Transition, Belarus

# 1 Introduction

Economic miracle - this is how many Belarusians were referring to the economic growth experience in the 2000s. Indeed, the growth rates were high and sometimes surpassed 10 percent per annum (see Figure 1). Growth was pro-poor, effectively reducing the poverty rate from 47 percent in 1999 to 5 percent in 2010 (World Bank, 2012; Haiduk and Chubrik, 2007). Even the recent crisis did not hurt Belarusian economy much: in 2009 the growth rate was close to zero, but still positive. Due to this steady growth in terms of PPP-converted GDP per capita in 2010 Belarus was lagging behind only the three Baltic states and the Russian Federation out of all the post-Soviet countries (Heston, Summers and Aten (2012)).

Figure 1: GDP growth rates and investment rates in Belarus, 2000-2012

The miraculous part is that Belarus differs strikingly from the other post-Soviet or transitional success stories. Unlike the Baltic states, it did not reform its economy and did not integrate with the EU. Belarus did not experience full-scale privatization, and many major enterprises remain in the state ownership or under state control. Also it did not pay enough attention to the development of the private sector until recently. Belarus also failed to attract significant amounts of foreign investments. Foreign sources contributed only 3.48 percent of the total investment in 2001-2010. According to the overall index of transition reforms (Dell’Anno and Villa, 2013) Belarus is the penultimate among the other transition countries, outrunning only Turkmenistan. Unlike Russian Federation, Belarus does not have oil or gas, and potassium salts are the main and modest source of natural resource rents.

Despite the unique growth experience of Belarus, literature on growth in Belarus is scarce, to the best of our knowledge. Demidenko and Kuznetsov (2012) and World Bank (2012) used official capital estimates to perform growth accounting and found significant contributions of TFP to growth. We argue that the official statistics on capital is plagued with measurement problems,

mostly due to high inflation rates (this is for many transitional countries, see, for example Bessonov and Voskoboynikov, 2008). We reconstruct the capital series using the capital services approach. We use the reconstructed capital for the growth accounting procedure and to estimate and compare TFP residuals.

Our central finding is that capital accumulation was the main source of growth in 2006-2010 in Belarus. In this regard Belarus follows the pattern of growth in the post-war USSR (Ofer, 1987). While many transitional and developing countries experience productivity growth in manufacturing, in Belarus manufacturing TFP was roughly stagnant. We also find that directed lending programs, initially designed to promote growth, cause capital misallocation and diminish aggregate TFP.

We compare TFP in Belarus to TFP of another transition country, the Czech Republic, and a developed country, Sweden. Belarus is relatively in closing the TFP gap with Sweden. Also, Belarus is lagging behind in productivity in the tradeable sector, which may explain present deficits of the current account.

The paper proceeds as follows. In Section 2 we discuss our choice of methodology for the growth decomposition and TFP comparisons. Section 3 describes the data, and the procedure to reconstruct capital series. Section 4 presents the results of the growth accounting exercise for the economy of Belarus and its industries. Section 5 compares aggregate and sectoral productivity in Belarus, the Czech Republic and Sweden. Section 6 offers conclusions and policy recommendations.

## 2 Methodology

### 2.1 Selecting proper strategy

Growth accounting and TFP comparisons are widespread elements in the literature on productivity analysis. However, the purposes and the methods of these exercises differ. By the criteria of computational methods and applicability of its results Islam (2001) aggregates existing strategies into three major approaches: (i) time-series (either in absolute or relative form); (ii) cross-section; (iii) panel regression. From the view of the applicability of results, cross-section and panel regression approaches are mainly intended for cross-country comparisons of TFP levels, growth rates, factors and sources of growth. This is done through bringing time-series data of different countries to a common denominator.

In our case, we do pursue the objective of incorporating Belarusian economy and its industries into inter-country comparisons, but along with in-country analysis. The latter assumes the comparison of productivity levels, dynamics and its sources among the industries of Belarusian economy as

well. So, having both objectives in mind, we fall back upon time-series approach (both in absolute and relative form).

Absolute form of time-series approach consists of comparisons of TFP growth rates that are computed basing on standard growth accounting procedure (Young, 1995 is probably the best-known example, while Barro and Sala-i-Martin, 2004 offer a textbook treatment of this procedure). This approach mainly strives for dissecting the factors of output growth. It is expected to answer the question which share of growth can be contributed to inputs (labor, capital, and sometimes human capital) and which to the growth of productivity.

Relative form of time-series approach is mainly focused on the computations of TFP levels, which widens the boundaries of productivity analysis. TFP levels seem to be of particular interest from the view of studying the level of competitiveness. Moreover, TFP levels effectively supplement growth context by offering information on initial points and stages of growth.

## 2.2 Specification of production function

The specification of production function predefines differences in computational strategies within time-series approach.

According to the first criterion, the simplest option assumes the use of Cobb-Douglas production function. This computational strategy was initially introduced by Tinbergen (1942), and continues to be employed nowadays (IMF, 2010, World bank, 2012). Most frequently, growth accounting exercise based on the Cobb-Douglas production function considers only the aggregate level, i.e. the entire economy. In this case, the shares of factor inputs usually are imposed (with the conventional values of 0.6 the share of labor, and 0.4 the share of capital). Another option is to compute the labor share from the income account. Independent on the source of the data, income share is constant through the entire sample and does not considerably affect the results of the estimation in terms of the growth rates.

More general and complicated specifications of production function are used when there is enough information to estimate the parameters of such specifications. Many authors use translog function to analyze production (Young, 1995; Christensen, Cummings and Jorgenson 1981). This specification of production function allows addressing the problems of aggregation. First, the issue of aggregation matters when the inputs are considered to be not homogenous, but a combination of different classes of sub-inputs. Second, the aggregation issue arises when the growth and its sources at the macro-level are aimed to be decomposed by industries of the economy. In both cases, proper weighting of the sub-elements matters for correct computation of productivity indicators.

Briefly, the basic advantage of translog production function may be interpreted as the opportunity to consider the shares of factor inputs as non-constant indicators that vary because of changing composition of correspondent aggregates. This advantage seems to be of particular importance when dealing with TFP levels. However, when undertaking analysis in terms of growth rates, one may mainly overcome the problem of aggregation by constructing a variable which is a Tornquist weighted average of its components. This growth accounting approach is mainly used in KLEMS studies (for instance, see Timmer et al., 2007 and 2010).

For our study, we need a computational approach that enables us: (i) to fulfill a growth accounting procedure, both at the aggregate level and at the level of industries; (ii) to compute and compare TFP levels of Belarusian economy and its industries with benchmark countries. Jorgensons methodology (Christensen et al., 1981, Jorgenson et al., 2005) seems to be the best option for joint and coherent analysis of both levels and growth rates. However, the lack of available data (in order to estimate the translog production function) is the obstacle to replicate this methodology in respect to Belarus.

Furthermore, there are two obstacles for feasible assessments of factor inputs shares in Belarusian economy. First, the assumption of factor markets competitiveness in Belarus is far from being fulfilled, which forms a gap between factors actual revenues and its marginal product. Second, a number of considerable inflation spikes during last two decades may determine a bias in correspondent estimations of factor inputs shares, as the latter assumes use of nominal parameters. Hence, in order to keep the conformity between the assessments in levels and growth rates we are to sacrifice the effect of changing shares of factor inputs. Through this, we resort to a most simple specification of production function, i.e. the Cobb-Douglas function, with a Hicks-neutral technical progress, (see Eq.1). We use this specification both on the level of the entire economy and for its individual branches.

$$Y_i = A_i K_i^{\alpha_i} L_i^{1-\alpha_i} \tag{1}$$

where  $Y$  is output,  $A$  is TFP,  $K$  and  $L$  are capital and labor,  $\alpha$  is capital share, and  $i$  is the industry index. The absence of the index  $i$  denotes the case of total economy.

### 2.3 Growth accounting procedure and computation of TFP level

From the Cobb-Douglas production function (1) we compute the level of TFP according to:

$$A_i = \frac{Y_i}{K_i^{\alpha_i} L_i^{1-\alpha_i}} \tag{2}$$

We must note that different measures of output – either gross output or value added – may enter production function (1) and TFP (2). The measure of the output determines the economic sense of the productivity (TFP) indicator. In our study, we constrain our analysis only to indicators based on value added. Using ones based on gross output according to (1) and (2) has little economic sense, since interpretation of the capital-labor total factor productivity based on gross output seems to be ambiguous. A meaningful measure of productivity based on gross output assumes that one more variable – intermediate inputs (energy, materials, services and other supplies) – should enter production function. However, adequate measurement of intermediate consumption in real terms, especially in industrial breakdown, is hardly possible for Belarus with a data set available.

Value added based indicators are the most popular in productivity studies. Nevertheless, rather frequently its economic sense is interpreted inaccurately, i.e. TFP level is expected to characterize technology only. However, this interpretation has plenty of caveats. First, the measure of productivity apart from technology also obviously includes measures of efficiency (understood as the distance between actual production point and production possibility frontier), economies of scale, capacity utilization, and measurement errors (OECD, 2001a and 2001b). Given that data on capacity utilization is mainly available (see Section 4.6), we can explicitly control the impact of the capacity utilization adjusting capital input by the correspondent rate. However, control of other components is hardly possible. Hence, we make simplifying assumptions that producers always operate at production possibility frontier and there are constant returns to scale, which means that TFP adjusted to the rate of capacity utilization ( $CU$ ) may be treated as a characteristic of technology.

$$A_i = \frac{Y_i}{(K_i CU_i)^{\alpha_i} L_i^{1-\alpha_i}} \quad (3)$$

In terms of growth rates, we carry out growth accounting exercise according to:

$$\frac{\Delta A_i}{A_i} = \frac{\Delta Y_i}{Y_i} - \alpha_i \frac{\Delta K_i}{K_i} - \alpha_i \frac{\Delta CU_i}{CU_i} - (1 - \alpha_i) \frac{\Delta L_i}{L_i} \quad (4)$$

### 2.3.1 Measuring allocative efficiency

Association of TFP with technology level is fully applicable (given the caveats mentioned above) in case when individual inputs and output are treated as integral ones, i.e. they cannot be disaggregated by components. We make such an assumption when dealing with industries of the economy. In other words, we treat each industry as an integral producer with its integral inputs, but not as the combination of output of individual firms with their individual inputs.

However, at the level of the entire economy such kind of disaggregation is possible. We consider total output and inputs as the combination of those of industries. Hence, TFP according to (3) in this case contains both characteristics of technology level and allocative efficiency. Allocative efficiency is broadly defined as the mix of inputs that produces a given quantity of output at minimum cost (Coelli et al., 2005). For our study, we elaborate the measure of allocative efficiency that is coherent with this definition.

First, we measure allocative efficiency in terms of output. For this, we solve an optimization (maximization) problem for output (see Equation 5), reallocating the one type of input among industries *ceteris paribus*, with a total amount of each input being given. Subsequently this problem is solved by reallocating capital or labor.

$$Y_k^* = \max_{K_i} \sum_{i=1}^n Y_i = \max_{K_i} \sum_{i=1}^n A_i (\bar{C}U_i K_i)^{\alpha_i} \bar{L}_i^{1-\alpha_i} \quad (5)$$

where  $\bar{L}_i$  and  $\bar{C}U_i$  are treated as fixed. We can define equivalently  $Y_l^*$  with maximization over  $L_i$ 's holding  $\bar{K}_i$  and  $\bar{C}U_i$  fixed (given by the data).

Using the optimal output from (5), we can define the measure of allocative inefficiency relatively to the aggregate output  $Y$ . Losses in output due to misallocation of inputs are the most explicit measure. Hence, we define the measure of misallocation  $M$  associated with an input  $j$  (capital or labor) according to (6).

$$M_j = \frac{Y_j^* - Y}{Y} \quad (6)$$

Third, we can integrate the measure of allocative inefficiency with our TFP measurement (3). Aggregate TFP residual  $A$  may be decomposed for technology indicator  $T$  and allocative efficiency indicator  $AE_j$ :

$$A = T + AE_j \quad (7)$$

We assign zero values to allocative efficiency indicators in case when an input  $j$  is allocated in an optimal way:

$$AE_j = 0 \text{ iff } M_j = 0 \quad (8)$$

The optimal (in terms of allocation of input  $j$ ) TFP level is defined according to:

$$A_j^* = \frac{Y_j^*}{(CU \cdot K)^\alpha L^{1-\alpha}} \quad (9)$$

Combining (7), (8) and (9) implies that optimal TFP level is identical to the technology level. Hence, in absolute terms we measure allocative efficiency associated with input  $j$  according to (10), and in growth rates according to (11).

$$AE_j = A - A_j^* \quad (10)$$

$$\frac{\Delta AE_j}{A} = \frac{\Delta A}{A} - \frac{\Delta A_j^*}{A} \quad (11)$$

## 2.4 International comparisons

TFP levels according to (3) are measured in national currency in constant prices of a particular year (2009 in our case). However, international comparisons require the indicators to be nominated in the same currency. Comparisons in international dollars seem to be the most reasonable for this purpose. However, instead of PPP concept that is more frequently used to internationalize the dollar in a number of studies, we resort to actual values of the exchange rate, which means that we are to use the index of real exchange rate of the national currency vs. US dollar. This choice allows to talk about the competitive advantages in international trade. According to this concept, for any nominal indicator  $X$  (nominated in national currency) that is the product of real quantity  $Q$  and price level  $P$ , its value in international dollar will be defined according to:

$$X_t^{b,int\$} = Q_t S_t \quad (12)$$

where  $X_t^{b,int\$}$  is a variable measured in international dollars  $int\$$  for a base period  $b$ ,  $Q_t$  is a real quantity measured in dollar prices of the base period,  $S_t$  is the real exchange rate index between periods  $t$  and  $b$  (with  $S_b$  set to 1).

The growth rate of the indicator in respect to the base (zero) period is defined according to:

$$\frac{X_t^{b,int\$}}{X_b^{b,int\$}} = \frac{Q_t S_t}{Q_b} \quad (13)$$

Hence, we can rewrite (12) in a following form:

$$X_t^{b,int\$} = X_b^{b,int\$} \left( 1 + \frac{\Delta Q}{Q_b} \right) S_t \quad (14)$$

However, in respect to TFP this concept cannot be used straightforwardly, as TFP is not a primary indicator. It is computed through other primary indicators (inputs and output) non-linearly. Hence, applying (14) to (3), we get (15):

$$A_{t,i}^{b,int\$} = \frac{Y_{b,i}^{b,int\$} \left( 1 + \frac{\Delta Y_i}{Y_{b,i}} \right)}{\left( K_{b,i}^{b,int\$} \left( 1 + \frac{\Delta K_i}{K_{b,i}} \right) CU_{t,i} \right)^{\alpha_i} L_{t,i}^{1-\alpha_i}} S_t^{1-\alpha_i} \quad (15)$$

We use the indicators computed according to (15) as TFP comparison indicators that measure efficiency in 2009-year international dollars.

### 3 Data: sources, characteristics, generation procedures

#### 3.1 The level of aggregation in dataset and sample periods

We carry out growth accounting procedure and make international comparisons of TFP on two levels of aggregation: (i) for the entire economy, (ii) for industries of the economy. For the entire economy this procedure is straightforward, as at the macro level Belarusian data for all the variables is available for 2005-2012. Breakdown by industries, however, is more problematic because of the shift in the system of classification of economic activity that was complete by the end of 2010. Before 2008, statistics was reported according to Soviet classification system (hereinafter, OKONH). This system was not comparable with any other international standard. In 2005, a shift to a new classification system (hereinafter, OKED) has been announced. OKED is the analogue of the statistical classification of economic activities in the European Community. OKED corresponds to version of NACE that was revised in 2002, that is usually treated as NACE Rev. 1.1 (hereinafter, NACE) with some minor adjustments to Belarusian context. In 2008-2010, which was an intermediary period, all the reports have been produced according to OKONH, but some of them simultaneously were produced according to OKED classification. Since 2011, only OKED classification is used in statistics. It should be emphasized that there is no direct concordance between economic activities in OKONH and OKED classifications. For broad economic activities (Section level according to OKED), Belstat has elaborated a generalized concordance table between OKONH and OKED. However, correct transformation of data from OKONH to OKED (and vice versa) according to this concordance table would require the data with a high level of disaggregation (up to 5 digits according to OKONH), which is not available. Hence, transformation of available data on value added, capital, and labor in OKONH classification to OKED classification is impossible.

We face a trade-off between the length of time period considered (historical data is available only in OKONH classification) and its closeness to present time (most recent data is available only in OKED classification). In order to keep both characteristics, at the level of industries we deal with two separate data samples that are formed according to different classification systems. The first sample is aimed to go back to historical values as long as possible and is classified according to OKONH. However, availability of the data (more precisely, data on capital; see Section 4.5 for more details) dictates a starting date for this sample, which is the year 2005. The upper bound is formed by data availability in OKONH classification, which is 2010. Hence, our first sample is 2005-2010 and it is organized by OKONH classification. Modest and flat inflation and absence of considerable structural shocks is an advantage of this period, which makes it a suitable representative period for Belarusian economy.

The second sample is aimed to provide evidence close to nowadays and is classified according to OKED. The starting point is formed by data availability (more precisely, labor; see Section 4.4 for more details) in OKED classification, which is the year 2010. The upper bound is formed by the availability of mostly fresh data, which is the year 2012. Hence, our second sample is 2010-2012 in OKED classification. OKED makes international comparisons possible. Furthermore, it provides most recent evidence about productivity.

### 3.2 The factor shares

Recent empirical literature (for example, Herrendorf and Valentinyi, 2008) suggests that factor shares differ substantially across industries. A standard approach to derive the share of factor inputs is to compute them directly in nominal terms using income-side disaggregation of value added. For our study, we exploit the system of input-output tables (more precisely, use tables in current prices) as the data source. The tables report the value added by each industry disaggregated by compensation of employees, gross profit, gross mixed income, and net taxes on production. Compensation of employees is the core of labor income in the economy, while gross profit and net taxes on production are associated with capital revenues. The standard problem is to allocate the mixed income between labor and capital revenues. For our exercise, we assign to each labor and capital 50 percent of gross mixed income. Hence, we treat the labor share as the relationship between the sum of compensation of employees and 50 percent of gross mixed income to value added, while the rest is associated with capital share (see Equations (16) and (17)).

$$\beta_i = \frac{W_i + 0.5MI_i}{VA_i} \quad (16)$$

where  $\beta_i$  is the labor share,  $W_i$  is the total employee compensation,  $MI_i$  is gross mixed income and  $VA_i$  is total value added in industry  $i$ .

$$\alpha_i = 1 - \beta_i \quad (17)$$

In case of Belarus, as shown above, two problems (lack of competitiveness at factor markets and huge inflation spikes) may hinder computation of factor shares according to (16) and (17). Furthermore, for individual industries a shift in the system of classification of economic activities during the period considered should be taken in mind, i.e. two separate data sets of factor inputs shares according to OKONH and OKED classification are to be generated. For OKONH classification we compute factor inputs shares basing on the data of 2005-2010. In these years inflation was modest and rather flat. Moreover, this period may be treated as the representative one for the structural relationships in the Belarusian economy. Hence, the estimates obtained on the data from this time period may be biased only because of lack of competitiveness.

For OKED classification, only the data for 2011 is available. However, use of this data leaves us little chances to assess correctly factor inputs shares for the OKED classification (i.e. since year 2011 and onward). First, one year is definitely not enough for reasonable assessment of factor shares. Second, this year (2011) stands out due to the currency crisis, huge inflation and correspondent adjustments in the national economy. Hence, factor inputs shares computed on 2011 data can hardly be considered as reasonable assessments of actual medium-term values. We resort again to data 2005-2010 according to OKONH classification and project it to OKED classification based on generalized concordance table (see Section 3.1) between two classifications. However, direct projection may be done only for the entire economy and for a few industries that are defined almost similarly in both classifications. If that a case, we consider the shares of labor in 2005-2010 to be the same for similar OKED industry. Further, we add an observation from 2011 and compute a labor share for an industry as the average of these 7 observations available. Otherwise, depending on the extent of concordance between industries according to OKED and OKONH, we assign weights to average of 2005-2010 and the value of 2011 years, and compute labor share for an industry as the correspondent weighted average. Obtained estimates for labor shares in industries are provided in Appendix A. For the entire economy, we get an average estimate of labor share in 2005-2010 of 0.595, which, however, goes down to 0.586 if the observation of 2011 is included. Nevertheless, in order to provide comparability with other studies (many of them set labor share to be 0.6, see, for example, Gomme and Rupert, 2007), we round up the value for the aggregate labor share to 0.6.

For a robustness check at the level of industries, we match our estimations with factor shares computed for Russia in Voskoboynikov (2012) (see Appendix A.2). This might be a good benchmark for comparison, as (i) characteristics of technologies in Belarus and Russia might be relatively close, given that just few industries have significantly changed technologies since the period of USSR; (ii) factor markets in Russia are much closer to the competitive stance rather than in Belarus (i.e. the actual revenues of correspondent factors are expected to be closer to their marginal product).

For the majority of industries, our estimates are close to those in Voskoboynikov (2012). There is, however, a significant difference among some essential industries: agriculture, trade and repair, and some manufacturing branches (chemicals, machinery and equipment, transport vehicles, etc.). However, for all this cases a reasonable justification dealing with technological issues may be found. For example, Belarusian manufacturing of transport vehicles mainly focuses on trucks, while the corresponding Russian industry focuses on cars. Belarusian chemical industry is extremely dependent on potash fertilizers, while the Russian chemical industry is more diversified.

### 3.3 Value added

The data source for the value added is the system of national accounts (hereinafter, SNA). Belarusian data according to SNA is reliable for a full period considered, as it has been produced in strict coincidence with international standards<sup>1</sup>.

SNA reports the value added both in current and constant prices. Within the period considered there was a shift in the base period for constant prices: the data for 2005-2009 is available in constant prices of 2005; the data for 2009-2012 is available in constant prices of 2009. In order to keep comparability between two our samples we recalculate value added in constant prices of 2005 into constant prices of 2009 (using correspondent growth rates). Hence, 2009 is the base period for prices in both our samples. In this manner we obtain value added in 2009 for the total economy and for industries of the economy according to OKONH.

However, this strategy does not work for obtaining the series of value added in sub-industries of the economy (more precisely, branches of the industrial sector<sup>2</sup>) according to OKONH. During the use of the OKONH classification, Belstat did not produce the estimates of value added for the branches of industrial sector using constant prices of a single year. For these branches the value added was calculated only in the prices of a previous year (for each year). We again use real growth rates for transforming available data to constant prices of 2009 year.

### 3.4 Labor input

We use the number of worked hours as the measure of labor input. This indicator is the product of an annual average number of employees and annual average number of hours worked per worker. These primary indicators are directly reported in labor statistics. For OKONH classification, they are available through 2005-2010, for OKED classification through 2010-2012.

### 3.5 Capital input

Among the factor inputs, just capital is usually characterized by high volatility that is consequent to volatility of investments. Hence, a proper approach to measuring capital input is vital for adequate computation of productivity and growth accounting exercise. However, many different measures of capital have been used in economic studies. The criteria on which they differ may be summarized as follows:

---

<sup>1</sup>For some other transition countries low quality of value added data, especially in industrial breakdown, is often a problem, as, say, double-deflation procedure is sometimes eliminated (see Voskoboynikov, 2012 for more details), and/or other drawbacks take place

<sup>2</sup>We use the term industrial sector in respect to the sector that according to OKONH classification contains OKED's manufacturing, production of electricity, gas, and water, and mining and quarrying.

1. Different concepts of capital: gross, net, or productive capital.
2. Different measurements: stock variable or flow variable.
3. Different sources of primary data: direct surveys of capital, investments data, firms' balance sheets, etc.
4. Different computational methods, techniques and assumptions.

For Belarus, feasible assessment of capital series is of particular importance, because the difference between available assessments is significant. The lower bound assessment for capital input is the official data. Belstat regularly reports real growth rates of capital according to gross concept. These growth rates display unnatural stability: during last two decades annual growth rate fluctuated around 2 percent. However, this dynamics of fixed assets does not match the dynamics of capital investments. The latter during last two decades (i) displayed rapid growth, (ii) this growth was rather volatile.

Bessonov and Voskoboynikov (2008) consider similar dynamics of official data in Russia. They argue that unnatural stability stems from biased investment deflators (they are overestimated) given the periods of hyperinflation in the beginning and late 90-s. Hence, the actual dynamics of capital input might be underestimated.

Rough estimates suggest that a core problem for Belarus is the same - biased investment deflators during the periods of high inflation. During the periods of relatively modest inflation, the biases are likely to exist as well, although they might not be so large. Given a number of specific features in the methodology of valuing capital in constant prices, the biases in investment deflator are accumulated and affect assessments for subsequent years. Hence, a U-shape form for the series of gross capital (in levels) is peculiar to Belarus (and to other countries that face such kind of problem).

Perpetual inventory method (hereinafter, PIM) is the most widely used method to recover the dynamics of capital stock. However, the use of PIM given biased deflators in general case cannot fully solve the problem of underestimation of growth rate of capital investments. Furthermore, depending on the primary data sources, estimates of capital may considerably differ under this computational method. For instance, Demidenko and Kuznetsov (2012) and World Bank (2012) apply PIM to data on inflows and outflows of capital. They obtain a raw series for the total economy that displays an extremely moderate growth rate (roughly 2 percent on average during 1995-2010). Hence, on the aggregate level they find that productivity was an engine of growth in Belarus. However, in IMF (2010), applying PIM to investments series, authors have obtained

different results. Their capital input demonstrates much more powerful dynamics, which signals about capital-based growth during the period they consider (1995-2008).

Direct use of PIM given biased deflators seems to be more reasonable if the series has been recovered starting from the period after high inflation, i.e. after the biases in deflators are mostly huge. So the estimates begin with contemporary period and go back to the past. Such kind of a technique (we call it PIM-backward) allows avoiding accumulation of biases. Hence, during the period without biases the actual values (and correspondingly growth rates) would be recovered. However, if the biased observations enter the sample, correspondent values of capital stock (in levels) would be underestimated, which results in overestimation of the growth rates through the whole period. Given this caveat, we may consider assessments according to PIM-backward as a likely upper bound for capital stock.

Apart from the problem of bias, straightforward use of PIM tends to be improper option in respect to Belarusian growth accounting study due to a number of reasons. First, for productivity studies the concept of productive capital (rather than gross or net capital) is much more reasonable. OECD (2001b) argue that the value of the capital services produced by an asset (not the value of the asset itself) is the actual contribution of the capital input to production process. Hence, OECD (2001b and 2009) recommend to use a volume index of capital services (flow variable) as the measure of capital input that enters the production function. The concept of productive capital and capital services obviously assume measuring capital input by each type of asset individually and proper aggregation of these inputs afterwards. Direct use of PIM does not meet these demands. However, PIM technique may be implemented within capital services computational strategy.

Second, residential housing in Belarus is accounted in mixed historical prices. The last broad-based revaluation of residential housing has been made in 2000. After that it has been made only fragmentary by individual legal entities. A revaluation of assets on average for the economy for 2002-2010 amounted to 214 percent, while for residential housing it amounted only to 34.5 percent, although anecdotal evidence suggests that housing prices grew more rapidly than the prices of other capital assets. The share of housing investments was growing during the last decade and its share has exceeded 20 percent of total investments. Given that housing investment measures actual inflow of new capital of such kind, while this part of capital stock is considerably undervalued, it is to contribute huge distortions to the measure of total capital. Furthermore, at the level of industries, different approaches to accounting of residential housing may alter the results of the exercise. For example, a huge part of residential housing in the rural areas is assigned to agriculture, while in the urban areas majority of residential housing is assigned to real estate industry.

Third, some industries practice purchase and sale of capital assets at the secondary market. For some of them, purchases/sales at the secondary market amount up to 15 percent of capital flows. However, statistics of capital investments to be used in PIM does not capture these flows.

For our exercise we use the concept of productive capital (capital services) and combine data sources to eliminate the problems peculiar to Belarusian statistics. We use annual statistics of direct capital survey and flows of capital as the primary source of data<sup>3</sup>. First, this statistical report provides a needed level of breakdown (by groups of capital assets for each industry) for a productive capital/capital services concept. Second, the problem of bias in investment deflators is automatically eliminated here. This problem mostly arises because of incorrect aggregation of individual deflators in aggregate index. In this data source, we have disaggregated deflators (individually for each group of capital assets for each industry). Furthermore, these deflators are calculated based on actual revaluation of capital assets by firms rather than on registration of prices on capital goods. Third, we exclude residential housing in our capital measurement (which, unfortunately, implies elimination of real estate industry for our analysis, as residential housing is a major part of its capital stock) as there is no possibility to measure residential housing correctly. Available breakdown by groups of capital assets allows us doing so. Fourth, use of this data source allows capturing the flow of funds between industries.

However, some drawback of this data source should be emphasized. First, this field of statistics suffers from incomplete coverage. This statistical form is reported by large and medium commercial firms only. Majority of state-owned educational, health institutions and those that provide social services are not recognized as commercial in this context and do not report this statistical form. Hence, we have to exclude corresponding industries in our exercise. Furthermore, this data source does not include the capital flows of small business.

Second, some industries display large and persistent differences between the dynamics of newly introduced capital assets and dynamics of capital investments. This is of particular concern for building material manufacturing, chemical and petrochemical manufacturing, and wood, pulp and paper manufacturing according to OKONH classification; for mining and quarrying, manufacture of leather, manufacture of wood, manufacture of rubber and plastics products, manufacture of non-metallic mineral products, hotels and restaurants according to OKED classification. Traditionally, statistics on capital investments is considered to be the most reliable one. Although in some cases difference in two strands of statistics may be explained by time needed to install the new equipment, we, nevertheless, tend to consider investment flows to be more meaningful in the context of productivity measurement. Hence, we prefer to rely on capital investments data for total volumes, but to keep all other advantages that are provided by direct survey data source.

The algorithm of measuring capital input is as follows.

---

<sup>3</sup>Official name in Russian is “Otchet o nalichii i dvizhenii osnovnyh sredstv i drugih oborotnyh aktivov”

1. *Defining age-efficiency profile for each single asset and for cohorts of assets.*

We follow recommendations of OECD (2009) to employ a profile with a constant percentage decline in efficiency for a cohort of assets (hereinafter, geometric pattern). OECD (2009) shows that there is empirical and theoretical evidence that supports use of geometric pattern in respect to combined age-efficiency/retirement profile for a cohort of assets. Furthermore, this kind of profile produces two huge benefits. First, there is no need to start with a profile for each single asset, as cohorts of assets may be treated straight away. Second, an identity between age-efficiency and age-price profile is kept for geometric pattern, which significantly simplifies the exercise. Thus, age-efficiency profile for the cohort of assets is defined according to:

$$g_{t,i} = \frac{P_{t,i}^\kappa}{P_{0,i}^\kappa} = (1 - \delta_i^\kappa) \quad (18)$$

where  $g$  is efficiency in standard efficiency units,  $p$  is the price of the group of assets,  $\delta$  is a depreciation rate and  $\kappa$  refers to a group of capital assets. We use the averages of accounting depreciation rates for  $\delta$ .

2. *Computing initial productive stock for each group of assets.*

Identity between age-efficiency and age-price profiles results in identity between net and productive capital stocks. Hence, we straightforwardly use net stocks for each capital good for the earliest date available (in current prices). For OKONH sample a starting point is January 1st, 2005; for OKED sample it is January 1st, 2008.

3. *Computing capital flows data (in current prices).*

We substitute the flows of newly introduced capital by each group of capital assets by corresponding capital investments according to:

$$CF_{t,i}^\kappa = \frac{I_{t,i} I_{t,i}^{\kappa,DS}}{I_{t,i}^{DS}} \quad (19)$$

where  $CF$  is a capital flow of newly introduced capital,  $I$  is capital investments,  $DS$  refers to direct survey of capital as a data source.

4. *Transforming initial stock and capital flows data to constant prices.*

We employ individual deflators for each group of asset in each industry. The base period for constant prices is the first year available in each sample: for OKONH sample we transform data to annual average prices of 2005 year, for OKED to annual average prices of 2008 year.

5. *Computing productive stock for each group of asset in each industry through PIM.*

First, we compute productive stocks for the beginning of each year, according to (20):

$$K_{t,i,bop}^\kappa = K_{0,i,bop}^\kappa (1 - \delta_i^\kappa)^t + \sum_{m=1}^{t-1} CF_{m,i}^\kappa (1 - \delta_i^\kappa)^{(m-0.5)} \quad (20)$$

where  $K$  is the productive capital stock,  $bop$  refers to the beginning of the period.

Afterwards, we compute an annual average productive stock as simple average between two consecutive values according to:

$$K_{t,i}^\kappa = \frac{1}{2} (K_{t,i,bop}^\kappa + K_{t+1,i,bop}^\kappa) \quad (21)$$

#### 6. Computing real user cost.

For each group of capital assets we compute real user cost  $RUC$  as the sum of real interest rate  $r$  and depreciation rate  $\delta$ :

$$RUC_i^\kappa = r + \delta_i^\kappa \quad (22)$$

As a rule, interest rates within a particular industry are considered to be equal for any capital asset (this is secured by free management structure within an industry). However, the rates may differ among the industries reflecting different returns. While there is an ambiguity in the data on actual interest rates and returns by industries, we chose to equalize the rates among industries and set them equal to 5 percent. This might cause some distortions, especially when there is actually a huge diversity in real interest rates among industries. On the other hand, this assumption allows eliminating the problem of subsidized interest rates that are peculiar to Belarusian economy.

#### 7. Aggregating capital inputs by different groups of capital assets and computing the volume index of capital services.

Real user costs are used as weights, and the volume index is obtained based on Tornqvist quantity index:

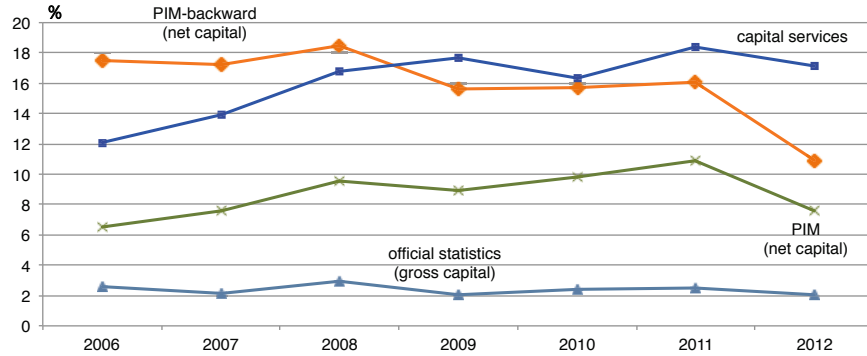

$$ICS_{t,i} = \Pi \left( \frac{K_{t,i}^\kappa}{K_{t-1,i}^\kappa} \right)^{\bar{\nu}_i^\kappa} \quad (23)$$

where  $\bar{\nu}_i^\kappa = \frac{1}{2}(\nu_{t,i}^\kappa + \nu_{t-1,i}^\kappa)$  and  $\nu_{t,i}^\kappa = \frac{RUC_i^\kappa K_{t,i}^\kappa}{\sum_{\kappa} RUC_i^\kappa K_{t,i}^\kappa}$ .

For the growth accounting exercise (4), we use (23) directly as the measure of capital input. However, for the computation of TFP levels (3) the variable that enters a production function needs some further development. Assigning the value of 100 to the base period (for each industry

in each country) would undermine the contribution of initial levels of capital intensity into TFP, so there will be a considerable loss of information from the view of international comparison. Hence, we use a level of net capital stock for a base period (2009 year) as the starting value, and apply growth rates of capital services volume index to it in order to obtain the levels of capital input for other periods.

Figure 2: Growth rates of capital under different approaches

For a total economy, our basic measure for capital input (in comparison with measures from other approaches) is provided in Figure 2.

### 3.6 Capacity utilization

The main data source for capacity utilization is the survey of the firms prepared by the National bank of Belarus<sup>4</sup>. However, the Bank does not report capacity utilization rate for all the industries that are engaged to our study. For OKONH classification, the data on agriculture, communications, finance, credit, and insurance are absent. In respect to OKED specification, the data is missing for fishing, hotels and restaurants, financial activities, and branches of manufacturing. In case of missing data, we ground our assumptions on the available data for production of representative goods for a correspondent industry that are reported by Belstat. Another option is to link the dynamics of the industrial capacity utilization with those for the total economy, given either available or projected starting point.

<sup>4</sup>Official source name in Russian is 'Monitoring predpriyatiy realnogo sektora ekonomiki Respubliki Belarus'

## 4 Sources and patterns of growth in Belarus

### 4.1 Growth accounting for the aggregate economy

Growth accounting exercise is treated as the procedure that gives a primary diagnostics of growth and visualize the contribution by each factor input and productivity. Macroeconomic basics assume that sustainable economic growth depends critically on the productivity growth. Other factor inputs have diminishing marginal returns. Hence, accumulation of factor inputs only may generate growth only until optimal (stationary) factor deepness has been achieved. Afterwards, only growth of productivity may generate sustainable growth.

Decomposition of growth for the entire Belarusian economy in 2006-2012 shows that the growth was driven by the accumulation of capital (see Figure 3).

Figure 3: Contributions of different factors and TFP to growth in Belarus, 2006-2012

At first sight, this diagnosis is not that surprising and disappointing. For instance, a capital-based growth is a widely accepted diagnosis for the countries that rely on catch-up strategy. For instance, Young (1995) demonstrated that accumulation of capital explains a huge part of growth in majority of Asian tigers through 1960-1990. However, in their case, rapid capital growth was accompanied by “not particularly low, but not extraordinary high productivity growth” (Young, 1995). However, in Belarusian case we must emphasize that capital was roughly the only engine of Belarusian growth (See Table 4.1).

This tremendous role of capital in Belarus worsens the diagnosis considerably. A country is expected to rely on extending productive capacities when the return on capital (marginal productivity of capital) is higher than its user cost. However, when the return on capital has reduced (due to accumulation of new capital), this strategy does not work anymore and additional injections of

Table 1: Average relative contributions to growth in value added, in percent

	2006-2010	2006-2012
Labor	-0.5	-5.3
Capital	81.5	98.3
Capacity Utilization	10.1	8.3
Productivity	9.0	-1.4
Gross Value Added	100.0	100.0

productivity are necessary to secure growth. Otherwise, growth rates will gradually decline to zero with further capital accumulation.

Hence, we argue that Belarusian growth during last years was not sustainable, as it was provided almost fully by capital input. Furthermore, we argue that a room for exploiting the strategy of capital extension has either exhausted, or at least is close to exhaustion: a rapid decrease in return on capital and its value approaching reasonable level of capital user cost signal about it (see Table 2). This view coincides with the evidence of sudden level shift in the growth rates by end of the last decade (see Figure 1).

Table 2: Marginal productivity of capital, in percent

	2005	2006	2007	2008	2009	2010	2011	2012
$MPK^*$	37.6	37.1	34.8	33	28.4	26.5	24.1	20.7
$MPK_{CU}^{**}$	52.1	49.4	45.1	41.6	36.3	33.4	30.3	26.1

\* Return on total capital accumulated, computed by  $MPK = \alpha \frac{Y}{K}$

\*\* Return on total capital employed, computed by  $MPK_{CU} = \alpha \frac{Y}{CU \cdot K}$

Finally, we argue that the lack of productivity gains is a major characteristic of recent growth in Belarus. While at the macro level productivity is strictly associated with the concept of national competitiveness, lack of productivity may be interpreted as poor national competitiveness. Furthermore, we admit that productivity growth should be the top priority for growth in Belarus.

## 4.2 Growth accounting for industries of the economy

The interest of growth accounting and productivity analysis at the levels of industries is threefold.

First, it answers the question whether the productivity path in the economy is the product of divergent paths of different industries, or it aggregates mostly monotonous paths by industries.

In the former case, poor gains in overall productivity may be associated with those in particular industries. The solution for this case might lie at the level of industrial policies and reallocation of resources only. However, if the latter case is on the agenda, the issue of systemic lack of productivity arises. It signals about unsatisfactory environment and vitalizes new growth enhancing incentives.

Second, productivity at the industrial level is traditionally treated as the measure of competitiveness. The ratio between productivity levels of two rivals (i.e. same industries) from different countries visualizes their relative (dis)advantages. This exercise assumes cross-country analysis (we produce it at Section 5). At the same time, comparison of productivity growth rates is worthwhile for in-country analysis, as it provides evidence about winners and losers in terms of progress in competitiveness. Furthermore, Levchenko and Zhang (2011) argue that there is a common trend that industries with a low initial level of relative productivity experience faster growth than those with a high initial level. This effect erases comparative advantages. While we do not have a benchmark for initial relative productivity level (it is possible to compare productivity levels only basing on OKED classification, i.e. since 2010), we make a distinction between high-grade and catch-up productivity growth in respect to in-country productivity level .

Third, the relationship of productivity growth rates between tradable and non-tradable sectors has implications for the development of real exchange rate. For instance, Harberger (1996) shows that if tradable sector is the leader in productivity growth, this is a likely precondition for the national currency to appreciate in real terms. However, if the productivity is driven by non-tradables, real exchange rate is expected to depreciate, *ceteris paribus*.

The results of growth accounting procedure for industries are reported in Appendix B.1. We can see that three sectors are distinct from an overall trend of capital-based growth: construction, communications, and finance and credit. In these sectors gains in productivity are responsible for roughly 50 percent of the observed growth. In overall, these sectors formed 16.4 percent of total value added in 2005-2010. Among them construction is of vital importance, because this sector is the largest - its weight was 10.3 percent - and it has displayed the most rapid productivity growth. However, there are some doubts on whether the progress in the computed TFP indicator actually was mainly caused by technological advances in the sector. One should take in mind that construction in Belarus (housing construction within it) is enormously dependent on directed lending programs. Directed lending generates additional artificial demand for the sector, which transforms into gains in TFP. But the other side of the coin is worsening productivity prospects in other sectors through a number of channels (Kruk and Haiduk, 2013). Hence, evidence in construction is not enough to argue that some huge industries follow the path different from the total economy.

Evidence of performance in communications and financial industry are better examples of productivity-based growth. However, because of their tiny weight in total value added these examples can hardly deny the conclusion that poor productivity performance is the systemic problem for the economy. Moreover, a huge part of productivity growth in communications may be explained by catch-up concept.

Table 3 reports the growth rates of productivity by industries of the economy given their initial relative positions in 2005. The development of TFP levels by industries does not display a bright

Table 3: Evolution of Industrial TFP Levels

	Relative TFP in 2005 (total economy=100)	Average TFP growth 2006-2010, percent
Construction	134.8	8.8
Communications	35	8.1
Finance, credit, insurance	89.4	7.7
Industrial sector	75.9	2.1
Other	49.4	6
Logging, wood, pulp and paper	109.2	5.1
Machinery and metal-working	142.1	3.9
Chemical and petrochemical	68.6	2
Fuel	16.3	1.9
Light industry	115.3	0.2
Ferrous metallurgy	62.1	-2.6
Food	100.8	-3.2
Building materials	118.1	-5.1
Electric power	50.6	-6.4
Agriculture	57.8	1.5
Trade and catering	145.4	-0.7
Transport	48	-0.7

distinction depending on the starting positions. Hence, the period considered does not provide enough evidence that initially productivity-depressed industries experience a faster productivity growth in respect to their domestic rivals. There are some examples of a catch-up pattern (communications, financial industry), which, nevertheless, has not become a common trend.

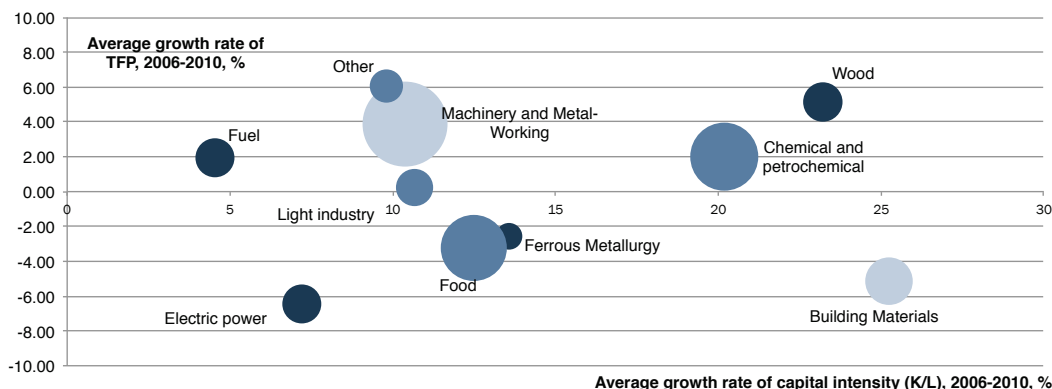

In respect to the breakdown of industries by tradeability of their production, we also see no pure trend. On the one hand, communications, construction, and financial industry that are the leaders in productivity growth are definitely refer to production of non-tradeables. On the other hand, trade and catering and transport that also mainly refer to sectors producing non-tradables are losers in productivity ranking. So, in this field, we may only argue that the industries producing

tradeables have not become strongly marked productivity growth leaders in the country. This implies that Belarus has not generated preconditions for appreciation of its exchange rate in real terms, while the latter is a common trend for majority of CEE transition countries. In other words, a medium-term trend of depreciation of real exchange rate reflects the problem of lack of competitiveness in production of tradeables.

### 4.3 Factor intensity and allocative efficiency

Productivity studies often implicitly expect that there is a strict relationship between capital intensity (i.e. the ratio  $K/L$ ) and productivity both in terms of levels and growth rates. For instance, Wolff (1991) supports this expectation (mainly in terms of growth rates) for the developed countries. He argues that countries with higher capital/labor growth generally had higher TFP growth. In case of Belarus our data neither support nor directly disprove this hypothesis (see Figure 4).

Figure 4: Capital intensity growth and capital growth in Belarusian manufacturing, 2006-2012

This ambiguity in impact of capital intensity growth gives a rise to doubts in effectiveness of strategy of rapid capital accumulation. Wolff (1991) highlights numerous channels that can generate a positive relationship between capital growth and TFP growth. An embodiment effect, which assumes that at least some technological innovation is embodied in capital, tends to be the most powerful in this context. But our methodology of generating capital series (the embodiment effect is expected to have been captured already in the capital data) and specification of production function are to crowd out this effect from the accounting and to visualize disembodied technological progress only. However, there are other channels (perhaps less powerful) which are to secure, nevertheless, a positive relationship between capital growth and TFP growth. First, the introduction of new capital may lead to better organization, management, and the like (Wolff, 1991). Second, the

learning-by-doing effect can positively affect productivity. Third, potential technological advance may stimulate capital formation, because the opportunity to modernize equipment promises a high rate of return to investment (Wolff, 1991). The last issue corresponds to a proper allocation of inputs, as the inputs are to move to those industries that experience higher returns.

Figure 5: Capital growth and TFP growth in Belarusian manufacturing, 2006-2012

Belarusian data suggests negative relationship between rates of capital accumulation and TFP growth (see Figure 5). A negative relationship implies that more capital leads to less efficiency, which tends to have little sense at the first sight. However, it does not look contradictory in light of Belarusian practice of directed lending (when the resources are allocated administratively to the industries basing on criteria other than returns on capital). For instance, Kruk and Haiduk (2013) emphasize a number of channels that determine less efficiency because of capital accumulation through directed lending procedures. They argue that allocative inefficiency (the capital comes to industries with low returns and distort incentives of the producers that obtain directed loans), liquidity shortage effect (underinvestment by productive firms), and financial intermediation inefficiency (savings rate is going to be damaged along with higher credit spreads) cause a trade-off between capital accumulation and TFP gains. A negative relationship between capital growth and TFP growth in Belarus provides additional evidence about existing trade-off between them. Furthermore, this evidence emphasizes the problem of improper allocation of capital, which leaves a huge room for TFP gains through better allocation.

A relationship between labor growth and TFP growth is also expected to be positive. Here the proper allocation prevails: growth in productivity is to raise labor productivity, which will attract more labor. Figure 6.A displays an ambiguous relationship: a group of industries exhibit clear positive relationship between TFP and labor growth (fuel, food, electrical energy, building

materials), while another group (machinery, woodworking, chemical production, and light industry) demonstrated gains in productivity vs. reduction of labor inputs. These two distinctive trends push us to account for the initial level of labor productivity, as a negative relationship is expected in case when the second group reduced labor given its initial excessive level. Figure 6.B presents a positive relationship between the level of labor productivity in 2005 and labor growth in 2006-2010, which supports the hypothesis of eliminating excessive employment. Industries which increased TFP and lost labor at the same time had low initial labor productivity.

Figure 6: Reallocation of labor in Belarusian manufacturing

Overall, we admit that the relationship between labor growth and TFP growth provides evidence that there is some room for efficiency gains due to proper allocation of labor, although this room seems to be much less than in respect to capital.

The issue of proper allocation seems to be of huge importance for Belarus. For a robustness check and in order to obtain additional measures of allocative inefficiency we assess correspondent losses in output (according to Eq.6) and contribution of allocative efficiency into TFP dynamics (according to Eq.11). We do this exercise for both samples OKONH 2005-2010, and OKED 2010-2012; and for three groups of industries: all industries with available data, for industrial sector (in OKED classification industrial sector is defined as the sum of mining and quarrying, manufacturing, and production and distribution of electricity, gas, and water), and for branches of manufacturing only. In first two cases (for all industries and for industrial sector) we impose an additional restriction that an input inflow/outflow from an industry should not exceed 40 percent of its actual level. The measurements of inefficiency in capital allocation are provided in Table 4, sections A and B.

Table 4: The measures of capital and labor allocation inefficiency

A. Capital allocation, 2006-2010 (OKONH sample)

	2006			2007			2008			2009			2010		
	T	IS	M	T	IS	M	T	IS	M	T	IS	M	T	IS	M
$M_k$	7.9	5.1	8.3	8.1	5	8.2	8.4	4.2	4.7	9	5.7	4.7	8.8	5.2	5.0
$\Delta A/A$	7.7	4.7	5.4	5.5	2.7	3.1	7.8	8.3	7.9	-3	-7	-6.1	3.5	3.5	4.1
$\Delta AE_k/A$	-1.1	0.4	1.7	-0.6	0	-0.1	-1	0.5	3.1	-0.4	-1.2	0.3	-0.1	0.3	-0.6

B. Capital allocation, 2010-2012 (OKED sample)

	2010			2011			2012		
	T	IS	M	T	IS	M	T	IS	M
$M_k$	10.5	8.5	6.0	10.8	9.1	5.5	10.8	10.1	8.0
$\Delta A/A$				3.4	-2.2	-1.0	-3.2	-2.8	-3.2
$\Delta AE_k/A$				-0.7	-0.6	0.4	0.0	-0.9	-2.3

C. Labor allocation, 2006-2010 (OKONH sample)

	2006			2007			2008			2009			2010		
	T	IS	M	T	IS	M	T	IS	M	T	IS	M	T	IS	M
$M_l$	2.8	1.7	2.1	2.7	1.8	2.3	2.6	1.7	2.3	2.8	1.4	1.9	3.1	1.7	2.2
$\Delta A/A$	7.7	4.7	5.4	5.5	2.7	3.1	7.8	8.3	7.9	-3	-7	-6.1	3.5	3.5	4.1
$\Delta AE_l/A$	-0.1	-0.1	-0.3	-0.1	-0.2	-0.3	-0.1	0	-0.1	-0.2	0.4	0.5	-0.4	-0.3	-0.4

D. Labor allocation, 2010-2012 (OKED sample)

	2010			2011			2012		
	T	IS	M	T	IS	M	T	IS	M
$M_l$	2.8	1.4	1.5	3	1.3	1	2.8	1.6	1.4
$\Delta A/A$				3.4	-2.2	-1	-3.2	-2.8	-3.2
$\Delta AE_l/A$				-0.2	0.1	0.4	0.2	-0.3	-0.3

Notes: T denotes to total economy (i.e. all industries for which the data is available), IS industrial sector, M manufacturing.  $M_k$  is computed according to (6) and measures output losses (as percentage from actual output) due to misallocation,  $\Delta AE_k/A$  is computed according to (11) and measures contribution of allocative efficiency into TFP growth in percentage points.

Overall, the data provides evidence that there is a huge room for efficiency increase just due to proper reallocation of capital: it may secure a single-shot increase of TFP and correspondingly output by from roughly 5 up to 10 percent of the actual level (depending on the set of industries considered). Estimations in respect to different set of industries provide evidence that inefficiency in manufacturing is lower than in a broader set of industries. The latter mainly stems from agriculture and electrical energy that are two most severe sources of misallocation. Furthermore, different sets of branches exhibit different evolution of inefficiencies over time and the increase in total inefficiency is again mainly associated with agriculture and electrical energy. Finally, during a period of high uncertainty and inflation (2011-2012), the volatility of inefficiency indicators increased, which reflects unstable environment at the financial markets.

The results of the similar exercise in respect to labor allocation suggests higher relative (i.e. in respect to capital market) effectiveness of labor market (see Table 4 section C and D). Losses in output due to misallocation of labor are systematically lower than those of capital. Furthermore, a difference in levels and growth rates is not so sensitive to the set of branches considered. Although total economy exhibits higher inefficiency (that again mainly stems from agriculture) than either the industrial sector or manufacturing, the gap is not that huge as in case of capital. A remarkable notice about labor allocation efficiency: it tends to improve during crisis years (2009 and 2011), while during fat years it mainly worsens.

## **5 Comparing Belarus to its neighbors: productivity in the Czech Republic and Sweden**

To understand how the performance of the Belarusian economy differs from the performance of other countries from the region, we compare it to the economies of the Czech Republic and Sweden. The Czech Republic is a leader of transition (Kornai, 2006; Winiecki, 2003) with one of the highest GDP per capita in the Central-European region. It is also comparable to Belarus in population, size, and (lack of) natural resources. We will compare both the growth patterns in Belarus and the Czech Republic, and the TFP levels of the corresponding industries and sectors of economy.

Sweden represents a technological frontier in our study. Sweden, like Belarus, is a socially oriented state (although the countries have different approaches to social policies), which imposes similar technological constraints on the production. Sweden also resembles Belarus in size and population. While little insight can be gained from comparing growth patterns of a developed economy like Sweden to developing economy of Belarus, we can compare TFP levels across countries to estimate how far Belarus is from the world technology frontier and what is the potential for the catch-up growth.

In this section we use the sectoral and aggregate data on real investments, labor input, capacity utilization and real value added from Eurostat. We reconstruct capital series from 2000 to 2011 for both countries with the perpetual inventory method in its traditional form. We use EU-KLEMS capital estimates (O'Mahony and Timmer, 2009) as the initial point for capital. We assume the depreciation rate is uniform across sectors and equal to 0.05.

Apart from the difference in the concept of capital, there is one more important difference between Belarusian and Czech/Swedish capital series: in Belarusian data investment and capital estimates are net of taxes on products, while European statistics provides gross capital formation series which include all taxes. We estimate that on average Belarusian capital series would be around 8 percent higher under the use of European statistical procedures. This discrepancy has no effect for the growth accounting results. However, it may affect our estimates of TFP differences.

## 5.1 Sources of growth in the Czech Republic

The Czech Republic has started its transition earlier than Belarus. It is also more developed: according to the Penn World Table data (Heston, Summers and Aten, 2012), in 1995 PPP-adjusted GDP per capita in the Czech Republic was 3 times higher than in Belarus. The income gap declined over time due to higher growth rates in Belarus. In 2010 GDP per capita (PPP-adjusted) in the Czech Republic was only 73 percent higher than in Belarus.

The sources of growth in Belarus and in Czech Republic also differ. Over the period of 2001-2010 the average annual growth rate in Czech Republic was 3.6 percent (compared to 7.4 percent in Belarus over the same period). Growth in aggregate productivity contributed 1.91 percentage points out of 3.6 percent in Czech economy, while in Belarus capital accumulation was the major driver of growth.

Capacity utilization also played important role for growth in the Czech Republic. Over our period of interest, 2000-2010, capacity utilization in manufacturing grew from 81.6 percent in 2000 up to 89.1 percent in 2007. Afterwards, however, capacity utilization dived to 76.3 percent over the Great Recession.

Appendices C.1 and C.2 present the results of growth accounting exercise for the major sectors and industries of the Czech economy in 2001-2010. We took into account capacity utilization for the branches of manufacturing. Manufacturing and trade, two largest sectors of the economy, were the major drivers of growth. But the sources of growth in those sectors differ: TFP was contributing to the growth in manufacturing, while trade grew mainly due to capital accumulation in this period.

Figure 7: Reallocation of capital and labor among industries of Czech manufacturing

In all the growing branches of manufacturing, like machinery, production of electrical equipment and transport vehicles, growth in total factor productivity was the main driver of growth. This is in line with the stylized fact that productivity growth is usually higher in the tradable sector.

As figure 7 shows, within manufacturing sector factors of production reallocated effectively to the industries with higher TFP growth. Growing industries like transport equipment manufacturing, machinery or electrical equipment manufacturing experienced increases in TFP, and also attracted capital and labor from other industries. This fact may suggest that factor markets in Czech Republic function more efficiently than in Belarus, where there is no positive relationship between TFP growth and growth in factors of production.

## 5.2 Comparisons of aggregate productivity levels: where is the Belarusian comparative advantage?

We used TFP residuals to compare productivity among the sectors and industries in Belarus, Czech Republic and Sweden. To convert the measures of output (value added) and capital into U.S. dollars, we used the real effective exchange rates (REER) as estimated by the central banks of the corresponding countries. REER-converted measures of TFP (according to Eq.15) reflect the competitiveness of the sector/industry in international trade. Any direct TFP comparisons are only indicative of the relative performance. Differences in the statistical methods, in particular in construction and quality of capital series may make them not directly comparable. However, since we can assume that the possible biases from the data are uniformly distributed across sectors and over time, relative TFP measures and their evolution over time can shed some light on the economic growth patterns in Belarus.

Figure 8: Catching up: Aggregate TFP in Belarus and Czech Republic relative to Sweden

We already know that TFP was growing relatively slower in Belarus than in the Czech Republic, and Figure 8 confirms it once again. We have chosen Sweden as a benchmark developed country and compare aggregate Czech and Belarusian TFP levels to it. The Czech Republic started out with the relatively higher level of TFP, but despite that it converged to Swedish level faster. Belarus managed to close only 9 percentage points of the gap over 2005-2009, while the Czech Republic diminished the gap by 13 percentage points. As a result, the gap between the two transition countries increased.

Table 5 lists the industries and sectors of Belarus economy which are the most and the least competitive in the relative TFP sense. Non-tradable sectors, namely trade and finance, have the smallest TFP differences with the developed Sweden. This finding is in agreement with Balassa-Samuelson argument (Balassa, 1964; Samuelson, 1964) and recent empirical findings by Herrendorf and Valentinyi (2012). Belarusian trade sector, both retail and wholesale, benefits from price-scissor practices in many domestic industries. Wholesale trade also often appropriates the benefits of low oil prices (along with the chemical industry) and other preferences from Russia. Food manufacturing is another benefactor of price-scissor practices in agriculture (UNDP, 2011). Demand-stimulating policies and relatively high real exchange rate also add to the relative success of non-tradable and consumption sectors like trade, finance or food manufacturing. Coincidentally, trade and finance are also the sectors with higher than average share of private ownership, which may also contribute to higher TFP (see evidence on higher TFP in Belarusian private manufacturing in Favaro, Smits and Bakanova, 2012).

Resource-based industries comprise another group of winners. The main natural resource in Belarus, potassium, gained the place in the champions list both for the mining and the chemical manufacturing sector.

Many of the industries "inherited" by Belarus from the Soviet Union end up on the list of underachievers. Machinery, electrical and transport manufacturing are among the main exporting

Table 5: TFP champions and underachievers in Belarus relatively to Czech Republic and Sweden

	Relative to	
	Czech Republic	Sweden
<b>Champions</b>		
Trade and repair	2.12	1.09
Chemicals	2.02	-
Mining and quarrying	1.35	1.01
Food, beverages and tobacco	1.24	0.57
Basic metals	1.20	0.61
Financial activities	1.15	0.81
<b>Underachievers</b>		
Textiles and leather	0.73	0.27
Machinery and equipment	0.71	0.34
Wood	0.68	0.29
Electrical, electronic and optical equipment	0.65	0.22
Transport vehicles and equipment	0.63	0.58
Electricity, gas and water	0.25	0.27

2010 TFP residuals, REER-converted. Belarusian TFP values (capital services approach) relative to the corresponding sector or industry of Czech and Swedish economies.

sectors, and given the low relative TFP levels, it is not surprising that these exports are not successful in the EU and are deteriorating in Russia. Textiles and wood manufacturing are two industries which have become proverbial of the failing state management and modernization efforts in Belarus. Government-controlled sector of the provision of electricity, gas and water is notoriously inefficient and suffers from the price controls by the government and non-clear subsidizing schemes (World Bank, 2013).

See Appendix D for detailed report of REER-converted TFP levels in 2010.

## 6 Conclusions

Over the period of 2006-2010 capital accumulation was the major source of economic growth in Belarus. It explains over three fourths of the average annual growth rate of 7.53 percent in value added. Increase in capacity utilization also contributed to growth more than increase in TFP, which constitutes only one tenth of growth. This extensive growth reminds of the Soviet growth pattern and has already led to expected economic slowdown. Further capital accumulation and increases in the capacity utilization will have limited effect on growth.

More capital, however, is not always a good thing. On the sectoral level, industries and sectors with relatively low capital-output ratio, along with a high level of competitiveness and involvement of foreign capital, like trade and finance, tend to be more productive. The only exception here is construction, which benefited from the directed lending policies of the government.

The slow growth of aggregate productivity is aggravated by the misallocation in capital markets. Capital accumulation does not accompany the growth of productivity for the majority of industries. On the contrary, for some industries excessive capital accumulation might be an obstacle (or a substitute) for productivity growth. Because of improper allocation of capital, Belarus loses about 5 to 10 percent of its actual output. More flexibility on the capital market and less directed lending practices will result in better capital allocation and provide considerable single-shot increase in output.

In the context of long-term growth strategy, a trade-off between capital accumulation and TFP growth gives a rise to doubts about the efficiency and prospects of capital-driven TFP progress. At the same time, there is a huge room for disembodied TFP growth, for example, by building a system of proper incentives, effective regulation and efficient allocation of resources. Moreover, the latter strategy seems to be less costly in terms of short-run macroeconomic disturbances and financial expenses.

Labor markets are more efficient in allocation. A significant number of industries increase their productivity due to elimination of excessive labor employment. Positive association between productivity growth and labor input is peculiar only to finance, construction and fuel industry.

Despite high aggregate growth rates, Belarus is lagging behind other transitional countries in aggregate productivity. In particular, the productivity gap with the Czech Republic is not diminishing over time. The lag in TFP resulted in the crisis of the comparative advantage, causing systemic trade deficits and, in particular, currency crisis of 2011. Indeed, the Belarusian productivity advantages are concentrated either in the non-tradable sectors like trade and finance, or natural-resource based like chemical manufacturing or mining.

To escape the trap of slow economic growth and poor international competitiveness, Belarus should concentrate on policies promoting TFP growth. The misallocation of capital, for example, represents an untapped resource of growth through reallocation of resources to the more efficient industries and firms. High TFP gap in comparison to the developed Sweden suggests there is room for growth through technology adoption. Policies aimed at promoting competitiveness and better state-owned enterprise management (in particular, through privatization) will create incentives and conditions for technology adoption.
