A BAYESIAN LOOK AT DIAGNOSTICS IN THE UNIVARIATE LINEAR MODEL

Irwin Guttman and Daniel Peña*

Abstract

This paper develops diagnostics for data thought to be generated in accordance with the general univariate linear model. A first set of diagnostics is developed by considering posterior probabilities of models that dictate which of $k$ observations form a sample of $n$ observations ($k < n/2$) are spuriously generated, giving rise to the possible outlyingness of the $k$ observations considered. This in turn gives rise to diagnostics to help assess (estimate) the value of $k$. A second set of diagnostics is found by using the Kullback-Leibler symmetric divergence, which is found to generate measures of outlyingness and influence. Both sets of diagnostics are compared and related to each other and to other diagnostic statistics suggested in the literature. An example to illustrate the use of these diagnostic procedures is included.

Key words:
spurious and outlying observations; posteriors of models; leverage; Kullback-Leibler measures; outlying and influential observations.

ABSTRACT

This paper develops diagnostics for data thought to be generated in accordance with the general univariate linear model. A first set of diagnostics is developed by considering posterior probabilities of models that dictate which of $k$ observations from a sample of $n$ observations ($k < n/2$) are spuriously generated, giving rise to the possible outlyingness of the $k$ observations considered. This in turn gives rise to diagnostics to help assess (estimate) the value of $k$. A second set of diagnostics is found by using the Kullback-Leibler symmetric divergence, which is found to generate measures of outlyingness and influence. Both sets of diagnostics are compared and related to each other and to other diagnostic statistics suggested in the literature. An example to illustrate the use of these diagnostic procedures is included.

Key Words: spurious and outlying observations; posteriors of models; leverage; Kullback-Leibler measures; outlying and influential observations.
1. INTRODUCTION.

According to Webster's dictionary, Diagnosis is the art of inferring from symptoms or manifestations the nature of an illness or the cause of a situation. One of the most serious illnesses that can occur in linear statistical model situations is the presence of outliers, and this fact has motivated the creation of the whole area of robust estimation and outlier testing. From the Bayesian point of view the study of outliers in linear models has already induced a long tradition. In a seminal paper, Box and Tiao (1968) showed that assuming a normal contaminated distribution for the generation of the observations of a linear model, the estimation of the parameters involve a weighted average of estimators from $2^n$ distributions. These $2^n$ distributions are obtained by considering all the possible cases of subsets of the $n$ observations belonging to the contaminating distribution. Although they were more concerned with estimation than with outlier identification, their approach leads to diagnostics for model heterogeneity, further investigated in Peña and Tiao (1992). Abraham and Box (1978) introduced heterogeneity in the mean instead of in the variance. This mean-shift model was also suggested by Guttman, Dutter and Freeman (1978). These models have been compared in Eddy (1980), Freeman (1980), and Pettit and Smith (1985).

In Section 3 of this paper we shall show that one of the diagnostic measures we suggest can be justified if sampling is from either one of aforementioned models.

Zellner (1975), Zellner and Moulton (1985) and Chaloner and Brant (1988) define outliers as extreme observations arising from the model under consideration and do not view these as being generated from a mean-shift or variance-shift model. Outliers are then detected by examining the posterior distribution of the random errors.

Since the work of Cook (1977), Cook and Weisberg (1982) and Belsley, Kuh and Welsch (1980), the study of influential observations in a linear model has been an area of very active research. Johnson and Geisser (1983, 1985) built measures of influence in univariate and multivariate linear models by using the Kullback-Leibler divergence between
certain predictive or posterior distributions. Related work is found in Pettit and Smith (1985). Guttman and Peña (1988) showed, using the same approach, that a global influence measure built from a certain joint posterior distribution can be decomposed into a measure of outlyingness and a measure of influence and that this Bayesian diagnostic encompasses the frequentist diagnostics for outliers and influence. Related work can be found in Ali (1990). Kempthorne (1986) used a formal decision-theoretic set up to justify influence measures in a Bayesian framework. In a similar spirit, Carlin and Polson (1991) have justified taking the Kullback-Leibler divergence as the utility function and have shown how to compute diagnostics using the Gibbs sampling method.

The objective of this paper is (i) to present diagnostics for heterogeneity based on mean shift or variance-shift models, and (ii) to present diagnostics based on measures of influence derived from Kullback-Leibler divergences. Doing this requires different approaches and assumptions, so that a further objective is to show the relationship of the diagnostics found from (i) and (ii).

In Section 2, we describe two variants of the usual linear model which allows for the generation of spurious observation, namely the so-called ‘mean-shift’ and ‘variance-inflation’ models. In Section 3, we derive our first diagnostic $C_l$, the conditional posterior probability that for given $k$, a certain set of $k$ out of $n$ observations are generated by the mean-shift model, and show the connection of $C_l$ with the leverage of these $k$ observations. We also demonstrate that $C_l$ is approximately for large $n$, the conditional (on $k$) posterior probability that the $k$ observations have been generated according to the variance-inflation model. Section 4 allows for diagnostics concerning the determination of $k$. The Kullback-Leibler divergence is used in Section 5 to measure the disparity between various posteriors based on the full sample with those based on a set of $n-k$ observations. With the measures obtained in Section 5, we turn to comparing the behaviour of $C_l$ and the Kullback-Leibler induced diagnostics in Section 6. We then indicate in Section 7, how a procedure using all these diagnostics would proceed by illustrating with a real set of data.
2. THE GENERAL SETTING.

We will be concerned with the analysis of data thought to be generated in accordance with the general univariate linear model, universally denoted as

\[ y = X \beta + \varepsilon \]  

(2.1)

where

\[ X \text{ is } (n \times p), \quad r(X) = p < n \]

\[ \beta \text{ is } (p \times 1) \]

(2.1a)

\[ \varepsilon \text{ is } N(0, \sigma^2 I_n) \]

We envisage that although (2.1) is the intended situation, the experimenter fears (because of experience) that some observations, say \( y_{i_t}, \quad t = 1, \ldots, k \), with \( k \) fixed and such that \( k << n/2 \), are spuriously generated, with mean-shift spuriosity parameter \( a_t \), that is

\[ E(y_{i_t}) = x_{i_t} \beta + a_t \]

(2.2)

We denote the set \( \{i_1, \ldots, i_k\} \) by \( I \), that is, \( I \) is the set of \( k \) distinct integers chosen from the set \( \{1, \ldots, n\} \). The use of the term "Spurious" above implies that the observations indexed by the set \( I \) were generated not in the manner intended (as described by (2.1)), but specifically by the generation process (2.2), called the mean-shift spuriosity model.

If for a given set of observations indexed by \( \{i_1, \ldots, i_k\} = I \), (2.2) holds, then after permutation we may write

\[ \begin{pmatrix} y(i) \\ y_I \end{pmatrix} = \begin{pmatrix} X(i) \\ X_I \end{pmatrix} \beta + \begin{pmatrix} 0 \\ a \end{pmatrix} + \varepsilon, \]

(2.3a)

where notationally, we mean:

\( (I) = \text{exclude or omit objects connected with the elements of } I = \{i_1, \ldots, i_k\} \)  

(2.3b)
so that, for example,

$$y_{(I)} = (y_{i_1}, \ldots, y_{i_{n-k}})'$$

(2.3c)

where the complement of $I$ is $\{i_1, \ldots, i_{n-k}\} \subset (1, \ldots, n)$. Further, $X_{(I)}$ is the $[(n-k) \times p]$ matrix found by omitting rows $(i_1, \ldots, i_k)$ from the matrix $X$ of (2.1); we use the notation $I$ to denote:

$$I = \text{use the data indexed by } I \text{ only.}$$

(2.3d)

We denote the model described by (2.3a) by $M_I = M_{i_1, \ldots, i_k}$, and we note that it says that $k$ observations $y_I = (y_{i_1}, \ldots, y_{i_k})'$, are generated spuriously, while the rest, that is, $n-k$ observations $(y_{i_1}, \ldots, y_{i_{n-k}})' = y_{(I)}$ have been generated as intended. We make one additional assumption, which is:

$$r(X_{(I)}) = p < n - k.$$  

(2.4)

We note that in the ensuing sections, the special case $k = 1$ will be delineated and discussed and for this situation we will use the notation $I = i$, etc.

We also note that if we knew that one of the $\binom{n}{k}$ models $M_I$ holds, and if we knew exactly which one of these holds, say $M_I$, then it would be natural to regress $y_{(I)}$ on $X_{(I)}$, forming

$$\hat{\beta}_{(I)} = (X_{(I)}'X_{(I)})^{-1}X_{(I)}'y_{(I)}$$

(2.5)

$$S_{(I)} = y_{(I)'(I)} - X_{(I)}(X_{(I)}'X_{(I)})^{-1}X_{(I)}'y_{(I)}$$

(2.5a)

etc. $S_{(I)}$ is the sum of squares of residuals based on what is thought to be the "good" data, $(y_{(I)}, X_{(I)})$, so that $S_{(I)}$ is a measure of scatter.

There are of course other models than (2.3a) for describing the generation of spurious observations - for example, we might have

$$
\begin{pmatrix}
Y_{(I)} \\
\vdots \\
Y_I
\end{pmatrix} =
\begin{pmatrix}
X_{(I)} \\
\vdots \\
X_I
\end{pmatrix} \beta +
\begin{pmatrix}
\varepsilon_{(I)} \\
\varepsilon_1 \\
\varepsilon_2
\end{pmatrix}
$$

(2.6)
with $\epsilon_I \sim N(O, \delta^2 I_k)$, but, as usual, $\epsilon_{(I)} \sim N(O, \sigma^2 I_{n-I})$ and where $\delta^2 > 1$. The model (2.6) is referred to as the variance-inflation model in the literature (see for example, Box and Tiao (1968)).

We turn now to our first diagnostic, and its use in a first part of a diagnosis of a set of data, namely a diagnostic to detect spurious observations.

3. DIAGNOSIS - PART 1.

Faced with the possibility that one of the mean-shift models $\{M_I\}$ as specified by (2.3a) holds, $I$ ranging over the $\left(\begin{array}{c} n \\ k \end{array}\right)$ sets of form $I = \{i_1, \ldots, i_k\}$, a Bayesian might want to calculate the posterior probability, say $c_I$, that $M_I$ holds, that is, that $(y_{i_1}, \ldots, y_{i_k}) = y_I$ is spuriously generated, and use the $c_I$'s as a set of diagnostics. It turns out that this probability, as derived by Guttman, Dutter and Freeman (1978), is given by

$$c_I = K^{-1/2} \left| X_{(I)}^T X_{(I)} \right|^{-1/2}$$

with

$$K^{-1} = \sum' S_{(I)} \left| X_{(I)}^T X_{(I)} \right|^{-1/2},$$

where $\sum'$ denotes sum over all the $\left(\begin{array}{c} n \\ k \end{array}\right)$ possible sets $I$.

To help interpret the role of $c_I$'s as diagnostics, suppose we consider first the simplest case, where $p = 1$, and it is thought that the generating process of the $y$'s is such that

$$E(y) = \mu$$

but it is feared that in a sample of $n$, that model $M_I$ holds, which is to say,

$$E(y_{i_t}) = \mu + \alpha_t, \; t = 1, \ldots, k$$

while

$$E(y_{j_u}) = \mu, \; u = 1, \ldots, n-k.$$  

Suppose indeed that the experimenter fears $M_I$ may hold for $k = 2$, and that a sample of $n$ yielded data which when plotted exhibits an extreme case such as depicted in Figure 3.1.
Figure 3.1. A sample of \( n = 10 \) observations

Now for this problem \( X = 1_{10} \), a \((10 \times 1)\) vector of ones, so that \( X(I) = 1_s \) as \( i \) ranges over the 45 different sets of 2 integers chosen from \( \{1, \ldots, 10\} \). Hence \( X(I) X(I) = n - k = 8 \) for all \( I \). Further, for this example, \( I = (i_1, i_2) \subseteq (1, \ldots, 10) \), and

\[
S(I) = y(I)[I_s - \frac{1}{n} I_s I_s] y(I)
\]

\[
= \sum_{j \neq i_1, i_2} (y_j - \bar{y}(I))^2
\]  

(3.4)

with \( \bar{y}(I) = \frac{1}{n-k} \sum_{j \neq i_1, i_2} y_j \). Hence

\[
C_I = \tilde{K}(S(I))^{-(n-k-p)/2} = \tilde{K}(S(I))^{-7/2}
\]

(3.5)

with

\[
\tilde{K}^{-1} = \sum (S(I))^{-7/2},
\]

since \( |X'_I X_I| = 8 \) for all \( I \). For this example, \( \sum' \) denotes the sum over all 45 sets \( I = (i_1, i_2) \) of 2 integer chosen from \( (1, \ldots, 10) \). Now as we cycle through the 45 different sets \( I = \{i_1, i_2\} \), we will eventually come to the set that excludes the minimum and maximum of the observations shown in Figure 3.1, so that the \( S(I) \) that we will then be concerned with, will be minimum amongst all the \( S(I) \), and since \( c_I \) is proportional to \( S(I)^{-(n-k-p)/2} = S(I)^{-7/2} \), the \( c_I \) for the case we are discussing will be largest, and in this extreme case, near 1.

We remark that \( c_I \) as defined in (3.1) can be expressed as a function of leverage. We first note that since \( X = (X'_I : X_I)' \),

\[
X'X = X'_I X_I + X'_I X_I
\]

(3.6)

so that

\[
|X'_I X_I| = |X'X| \cdot |I_p - (X'X)^{-1} X'_{I} X_I|
\]

\[
= |X'X| \cdot |I_k - X_{I}(X'X)^{-1} X'_{I}|
\]

(3.7)

7
Absorbing $|X'X|$ into the constant of proportionality $K$ of (3.1), we thus have that

$$c_I = KS(I)^{(n-k-p)/2} \cdot |I_h - H_I|^{-1/2}$$  \hfill (3.8)

with $K$ defined in the obvious way (see (3.1)), and where

$$H_I = X_I(X'X)^{-1} X'_I$$  \hfill (3.9)

is that block of the so called "hat matrix" $H$,

$$H = X(X'X)^{-1} X'$$  \hfill (3.10)

that is found by using columns and rows of $H$ indexed by $I = (i_1, \ldots, i_k)$. We note that for $k = 1$ we have

$$c_I = KS(1)^{(n-p-1)/2} \cdot (1 - h_i)^{-1/2}$$  \hfill (3.11)

where $h_i$ is the $i$-th diagonal element of $H$. Now the element $h_i$ is said to be the "leverage" of the observation $y_i$, and we note that if this is large (i.e., close to 1), then $c_i$ of (3.11), which takes the leverage of $y_i$ into account, tends to be large, since $c_i$ is increasing in $h_i$. For general $k$, $|I - H_I|^{-1}$ is a general function of the leverages of $(y_{i_1}, \ldots, y_{i_k}) = y'_I$ etc.

There may be a concern that the diagnostics $c_I$ are only useful for the mean-shift model (2.3a), and not at all useful for diagnostics concerning the variance-inflation model (2.6). Peña and Tiao (1992) address the question of diagnostics for the variance-inflation model (2.6), and it turns out that their diagnostics have an important and surprising connection with $c_I$. It turns out that, conditional on $Y$ containing $k$ spuriously generated observations, the posterior probability, say $p_k(I)$, that the set $Y_I$ is spuriously generated according to the variance-inflation model (2.6) is given by (see Peña and Tiao (1992))

$$p_k(I) = K_0 \left\{ \frac{|X'X|}{|X'X - \phi X'_I X' I|} \right\}^{1/2} \left\{ \frac{s^2}{\hat{s}^2(I)} \right\}^{\frac{n-k}{2}}$$  \hfill (3.12)
with
\[
\phi = 1 - \delta^{-2}, \quad (n - p)\delta^2 = S = y'(I - H)y.
\]
(3.12a)

As to \( s^2_{(I)} \), a precise definition is given in Peña and Tiao (1992), and it turns out that
\[
\lim_{t \to \infty} s^2_{(I)} = s^2_{(I)}
\]
where
\[
(n - k - p)s^2_{(I)} = S_{(I)} = y'[I_{n-k} - X_{(I)}(X'_{(I)}X_{(I)})^{-1}X'_{(I)}]y_{(I)}.
\]
Hence, if \( \delta^2 \) is large, so that \( \phi \approx 1 \), we have, on consulting (3.6) that
\[
\rho_K(I) = K_1S_{(I)}^{-\frac{n-k}{2}} \cdot |X'_{(I)}X_{(I)}|^{-1/2}
\]
(3.13)

which for moderate or large \( n \) is essentially \( \sigma^2 \).

A word here about \( k \), the “order” of the model \( M_f \). In practice, this is not known, but a realistic range of values for \( k \) may often be stated by the experimenter, based on his/his experience in the subject field, say \( 0 \leq k \leq k_0 \). [Interesting comments on the “choice” of \( k_0 \) have been made by Daniel (1959) and Box and Tiao (1968). If \( \alpha = \) Probability that an observation if spuriously generated, then these authors choose \( k_0 = \alpha n \), with \( \alpha = .10 \), with supporting arguments]. Hence a second part of the diagnosis involves “estimating” \( k \). This generates other diagnostic procedures, explained in Section 4, illustrated in Section 6.

4. TOWARDS COMPLETING THE DIAGNOSIS - PART 2

Diagnostics for \( k \) are readily available, but to describe this aspect of the diagnostic procedure, we now present some interesting results in themselves, which turn out to be useful in making diagnoses about \( k \).

We first assume that we are interested in making inference about \( \beta \), the regression coefficients involved in our linear model. It is well known [see for example, Box and Tiao]
We now explore the situation when one of the models $M_i$ holds for a given value of $k$. Then, as derived in Guttman, Dutter and Freeman (1978), it turns out that the posterior of $\beta$ takes the form

$$p(\beta | \text{data}; k) = \sum c_I h_p(\beta | \tilde{\beta}_I; \frac{n - k - p}{S_I} (X'_I X_I); n - k - p)$$

(4.7)

where $\tilde{\beta}_I$ and $S_I$ have been defined in (2.5) and (2.5a) respectively. That is, the posterior of $\beta$ is now a weighted combination of $p$-order multivariate $t$-densities, and a typical term says: omit $k$ $y$'s indexed by the set $I$ and compute the posterior based on the remaining data whose effective sample size is $n - k$ (see (4.1) and (4.7)), and weight that density with $c_I$, the posterior probability that the $k$ observations now ignored, are spuriously generated, or put another way, the density based on the $(n - k)$ observations indexed by the complement of the set $I$ is weighted with the probability that the $k$ observations indexed by the set $I$ itself should indeed be dropped.

Now using properties of the $p$-order $t$-distribution given in (4.3), we find that

$$E(\beta | \text{data}; k) = \sum c_I \tilde{\beta}_I = b_k, \text{ say}$$

(4.8)

and

$$E(\beta \beta' | \text{data}; k) = \sum c_I \left[ \frac{S_I}{n - k - p - 2} (X'_I X_I)^{-1} + \tilde{\beta}_I \tilde{\beta}'_I \right]$$

(4.9)

$$= D_k, \text{ say}$$

so that

$$V(\beta | \text{data}; k) = D_k - b_k b'_k.$$  

(4.10)

With these results in mind, we may now turn to the question of 'diagnostics' for the likely value of $k$. To begin with, suppose the values $x_{ju}, u = 1, \ldots, n$ of the $j$-th independent variable $(j = 1, \ldots, p)$ used to generate the $y_u$ are coded i.e., dimensionless variables. This would mean that each of the diagonal elements $V_{uu}$ of the variance-covariance matrix given in (4.10) are in the same units, namely, "$y^2$" units. Now a measure of
dispersion of the densities (4.1) and (4.7) is the trace (tr) of their variance-covariance matrices, and from (4.5) and (4.10) these are given by

\[
trV(\boldsymbol{\beta}|\text{data};k) = \begin{cases} 
\frac{n}{n-p-1} \, tr(X'X)^{-1} & \text{if } k = 0 \\
trD_k - b_k'b_k & \text{if } k \geq 0 
\end{cases}
\]  

(4.11)

Of course, (4.11) is in units of "$y^2$". We may now compare these traces for values $k = 0, 1, \ldots, k_0$. Now if a data set contains spurious observations which give rise to $k$ (extreme) outlying observations, then (4.11) tends to have a minimum as a function of $k$, about some value, say $\hat{k} > 0$, and we would use $\hat{k}$ as our estimator of $k$. This in turn means that we would use $p(\boldsymbol{\beta}|\text{data};\hat{k})$ - see (4.7) - to make inferences about $\boldsymbol{\beta}$. Of course, the $x_ju$'s could be in original units - for example, pressure in units of lbs./sq.in., time allowed for the process to run in minutes, temperature in °C, etc. Hence $V_{tt}$ is in units of "$y^2/x_j^2$", so that values of $trV(\boldsymbol{\beta}|\text{data};k)$ cannot be used.

But in this case, we can easily separately examine the diagonal elements $V_{tt}(k)$, and do this for each $t, t = 1, \ldots, p$. These minimums, usually, will be attained for each $t$ at the same value of $k$. (Of course, we can also do this for the previous case where $x_ju$'s are in coded units, $u = 1, \ldots, n; j = 1, \ldots, p$).

Another source of a possible diagnosis for $k$ is the $c_t$'s themselves. For each $k$ we may compute the $\binom{n}{k}$, $c_t$'s and note the maximum, say $c_t^*$ that is,

\[
c_t^* = \max_t c_t
\]  

(4.12)

We now do this for each $k = 1, \ldots, k_0$ and find

\[
c^{**} = \max_k c_t^*
\]  

(4.13)

The pattern of the individual $c_t$'s for given $k$ and the value of $k$ for which (4.13) is attained, together with the analysis of the variance-covariance matrices as described above, gives much information about the likely value of $k$. This is illustrated in the example of Section 7.
Before turning to an example, we discuss the use of the Kullback-Leibler information to generate other diagnostics for spuriousness, and, it turns out, of influence.

5. DIAGNOSIS: PART 3; THE USE OF KULLBACK-LEIBLER DIVERGENCE

The motivation for the approach of this section is as follows: Suppose (2.1) holds, so that in particular, all observations, have been generated as intended. Now consider the posterior $p$ of any or all the parameters of model (2.1), based on all observations, and contrast this with the posterior $p(I)$, the posterior based on the $n-k$ observations $y(I) = (y_{i1}, \ldots, y_{i_{n-k}})'$ with $k << n/2$. The pair $(p, p(I))$ should not differ too markedly, reflecting basically the same information about the parameters, except for the fact that $p(I)$ is based on fewer observations than $p$. So as we let $I$ range over the possible \(\binom{n}{k}\) available sets $I = (i_1, \ldots, i_k) \subset (1, \ldots, n)$, the pairs $(p, p(I))$ should differ in much the same fashion as each other.

Now suppose the $k$ observations $(y_{i1}, \ldots, y_{ik})$ have been generated spuriously (models (2.3) and (2.6) are examples) and we based our posterior on $(y_{i1}, \ldots, y_{i_{n-k}})$. Then we would expect much divergence between $p$ and $p(I)$, since $p$ is based on data that contains spuriously generated observations, while $p(I)$ does not. Of course, we do not know which set $(y_{i1}, \ldots, y_{ik})$ is the spurious set, so that we would like to examine the \(\binom{n}{k}\) possible cases, noting the pairs $(p, p(I))$ that seem to diverge markedly, thus indicating that $(y_{i1}, \ldots, y_{ik})$ has been generated spuriously.

The question, then, at this point is how to measure divergence between two densities. In this paper we utilize the Kullback-Leibler symmetric divergence, defined as follows.

**Definition 5.1:** If $f_1$ and $f_2$ are densities that are absolutely continuous with respect to measures $\mu_1$ and $\mu_2$, respectively, then the Kullback-Leibler information mea-
Lemma 5.1: Suppose $\mathbf{x}$ is a $(p \times 1)$ random vector variable whose density is one of
\[
f_j = \frac{1}{(2\pi)^{p/2}} \exp \left\{ -\frac{1}{2} (\mathbf{x} - \mu_j)' \Omega_j^{-1} (\mathbf{x} - \mu_j) \right\}
\]
($j = 1, 2$). Then the Kullback-Leibler divergence between $f_1$ and $f_2$ is
\[
J(f_1, f_2) = \frac{1}{2} (\mu_1 - \mu_2)' (\Omega_1^{-1} + \Omega_2^{-1}) (\mu_1 - \mu_2) + \frac{1}{2} \text{tr} \left( \Omega_1^{-1} \Omega_2^{-1} + \Omega_2^{-1} \Omega_1^{-1} \right) - p. \tag{5.4}
\]

The proof of this lemma is a straightforward application of (5.1) - (5.2) and left to the reader. We need Lemma 5.1 for the following situation. Suppose we assume that data is generated in accordance with
\[
\mathbf{y} = \mathbf{X} \beta + \epsilon, \quad \epsilon \sim N(0, \sigma^2 I) \tag{5.5}
\]
as in (2.1), and that the use of non-informative priors for $\beta$ and $\sigma^2$ is made, so that, in particular the posterior of $\beta$ is as stated in (4.1). This of course means that for moderate to large $n$,
\[
\beta | y \sim N(\hat{\beta}; s^2(X'X)^{-1}) \tag{5.6}
\]
Here, $s^2 = S/(n - p)$, where $S$ has been defined in (4.1a). [The symbol "\(\sim\)" means "approximately distributed as"]. Denote the density involved in (5.6) as $p$.

Now suppose our posterior is based on the data $(\mathbf{y}_{(I)}; \mathbf{X}_{(I)})$, where $\mathbf{y}_{(I)}$, $\mathbf{X}_{(I)}$, $\hat{\beta}_{(I)}$, and $S_{(I)}$ have been defined in Section 2. Then for moderate to large $n$,
\[
\beta | y_{(I)} \sim N(\hat{\beta}_{(I)}; s^2_{(I)}(X_{(I)}'X_{(I)})^{-1}) \tag{5.7}
\]
with $s^2_{(I)} = S_{(I)}/(n - k - p)$. Denote the density involved in (5.7) as $p_{(I)}$. Setting $f_1 = p$ of (5.6) and $f_2 = p_{(I)}$ of (5.7), we may now use Lemma 5.1 to state the following theorem.
Theorem 5.1. Using the above notation, and assuming (5.5) holds with \( n \) moderate to large, then

\[
J_\beta(p, p(I)) \approx p(D_1^2 + D_{1(I)}^2)/2 + \frac{s^2}{s_{1(I)}^2}(p - tr H_I)/2
\]

\[
+ \frac{s_1^2}{s^2}(p + tr H_I[I_k - H_I]^{-1})/2 - p,
\]

and

\[
\frac{s^2}{s_{1(I)}^2} = \frac{(n - p - k)}{(n - p)} \frac{(1 + e_I'(I - H_I)^{-1}e_I)}{(n - p - k)s_{1(I)}^2}
\]

\[
D_1^2 = e_I'(I - H_I)^{-1}H_I(I - H_I)^{-1}e_I
\]

\[
D_{1(I)}^2 = \frac{e_I'(I - H_I)^{-1}H_I e_I}{p s_{1(I)}^2},
\]

where, setting \( y = (y(I), y_I) \) and \( X = (X(I), X_I)' \), then the \((k \times 1)\) vector \( e_I \) is given by

\[
e = (e_I', e_I)' = (I - H)y.
\]

The proof of Theorem 5.1 is obtained by straightforward algebra using the results of Guttman and Peña (1988).

The quantity \( D_1^2 \) has long been advocated by Dennis Cook and fellow workers as a measure of influence - see for example Cook (1977, 1979) and Cook and Weisberg (1982) and the references therein. Of course, \( D_{1(I)}^2 \), then, is also a measure of influence, albeit in a slightly different metric than \( D_1^2 \). We remark that because of this, \( J_\beta \) of Theorem 5.1 is essentially a measure of influence, due to the presence of the terms \( p D_1^2 \) and \( p D_{1(I)}^2 \).

A Corollary to Theorem 5.1 for the special case of interest when \( k = 1 \) is the following:

We have denoted (5.8) by \( J_\beta(p, p(I)|k) \) in the following Corollary, and we note that when \( k = 1 \), then \( I = \{i_1\} \) which we may denote by \( i_1 \), \( i \) varying over \((1, \ldots , n)\).

Corollary 5.1.1. Setting \( J_\beta(p, p(I)|k = 1) = M_i(\beta) \), we have

\[
M_i(\beta) = p(D_1^2 + D_{1(i)}^2)/2 + \frac{s_1^2}{2s_{1(i)}^2}(p + \frac{h_i}{1 - h_i}) + \frac{s^2}{2s_{1(i)}^2}(p - h_i) - p
\]
where $h_i$ is the $i$-th diagonal element of $H$.

The proof of this Corollary is a straightforward application of Theorem 5.1 for the case $k = 1$. (Since $k = 1$, sets $I$ are singletons $i_1$, etc.) We will use $M_i(\beta)$ for all $n$ sets $i = \{i_u\}$, $u = 1, \ldots, n$ as diagnostics in our example of Section 7.

We may want to also inquire about the divergence between posteriors of $\sigma^2$, as we withdraw observations $(y_{i_1}, \ldots, y_{i_k})$. As is well known (for the case of non-informative priors), we have

$$
\sigma^2 | y \sim (n - p)s^2 / \chi_{n-k-p}^2, \quad (5.11)
$$

and

$$
\sigma^2 | y(I) \sim (n - k - p)s^2(I) / \chi_{n-k-p}^2. \quad (5.12)
$$

Identifying the posterior density of $\sigma^2$ in (5.11) as $p$ and that of (5.12) as $p(I)$, we have the following Theorem.

**Theorem 5.2.** Suppose (5.5) holds and non-informative priors are used, so that (5.11) and (5.12) applies. Then the posteriors of $\sigma^2$ of (5.11) and (5.12) have Kullback-Leibler symmetric divergence $J_{\sigma^2}(p, p(I) | k)$, which to order of $n^{-2}$ is

$$
J_{\sigma^2}(p, p(I) | k) = \frac{k}{2} \ln \frac{s^2(I)}{s^2} + \frac{1}{2} \left[ \epsilon^2(I) (J_k - H_k)^{-1} \epsilon(I) \right] \left[ \frac{1}{s^2(I)} - \frac{1}{s^2} \right]. \quad (5.13)
$$

The proof of this theorem is given in Guttman and Peña (1988).

The case $k = 1$ will be of special interest, and we have

**Corollary 5.2.1.** If $J_{\sigma^2}(p, p(I) | k = 1) = M_i(\sigma^2)$, then to terms of order $n^{-2}$,

$$
M_i(\sigma^2) = \frac{1}{2} \ln \frac{s^2(I)}{s^2} + \frac{1}{2} \left( \epsilon^2(I) - r_i^2 \right) \quad (5.14)
$$

where

$$
\epsilon_i^2 = \frac{\epsilon^2(I)}{s^2(I)(1 - h_i)}, \quad r_i^2 = \frac{\epsilon^2(I)}{s^2(1 - h_i)} \quad (5.15)
$$
with $e_i = e_i$, where we have set $i_1 = i$.

The Statistic $t_1$ defined by (5.15) has been extensively used in the literature as a test for spuriousness, and of course $t_i$ is a similar statistic using a slightly different estimator of $\text{Var}(e_i) = \sigma^2(1 - h_i)$ in its denominator. It can be shown that $M_i(\sigma^2)$ is an increasing function of $t_i^2$, and, hence is essentially a measure of outlyingness of $y_i$ [we have set $i_1 = i$, since $k = 1$ in the above].

Finally, we may ask about the divergencies of the posterior of $(\beta, \sigma^2)$, based on $y$ and $y(i)$ respectively. We have

Theorem 5.3. Suppose (5.5) holds, and non-informative priors are used. Then the Kullback-Leibler divergence between $p(i) = p(\beta, \sigma^2|y(i))$ and $p = p(\beta, \sigma^2|y)$ is, to terms of order $n^{-2}$,

$$J_{\beta, \sigma^2}(p, p(i)|k) = \left[ \frac{e'_i(I_k - H_I)^{-1}e_i}{2} \right] \left[ \frac{1}{\sigma_i^2} - \frac{1}{\sigma^2} \right] + \frac{1}{2} tr(H_I[I_k - H_I]^{-1}H_I) + \frac{k}{2} \ln \frac{s^2(I)}{s^2(i)}.$$

(5.16)

The proof of this Theorem is given in Guttmann and Peña (1988). This proof uses a key relation about conditional-unconditional divergences used for a more general model by Johnson and Geiser (1985). For the special case $k = 1$, we have:

Corollary 5.3.1. Letting $J_{\beta, \sigma^2}(p, p(i)|k = 1) = M_i(\beta, \sigma^2)$, then

$$M_i(\beta, \sigma^2) = \frac{1}{2}(t_i^2 - t_i^2) + \frac{1}{2} \left[ \frac{s^2(i)}{s^2(i)} D_i^2 + \frac{s^2(i)}{s^2(i)} D_i^2 \right]$$

+ $\frac{1}{2} \frac{h_i^2}{1 - h_i} + \frac{1}{2} \ln \frac{s^2(i)}{s^2(i)}.$

(5.17)

With the above Theorems and Corollaries in mind, we now turn in the next Section to a description of their behaviour, which will help map a strategy on how to use these results in a diagnostic procedure.
6. THE COMPARISON OF THE VARIOUS DIAGNOSTIC MEASURES

We have presented various statistics to identify spurious observations. These are the probability \( c_I \), and the distance \( J_I(\beta, \sigma^2) \). We have also shown that this latter portmanteau measure is related to the specific measures \( J_I(\beta) \) and \( J_I(\sigma^2) \), which, of course, can be used to identify influential and outlying observations.

To illustrate the relationship between \( c_I \) and \( J_I(\beta, \sigma^2) \), let us consider the case \( k = 1 \). Then, (5.17) can be written as, after some algebra

\[
M_i(\beta, \sigma^2) \approx \frac{r_i^2}{2} \left[ \frac{s_i^2}{s_i^2} \frac{1}{1 - h_i} - (1 - h_i) \right] + \frac{1}{2} \frac{h_i^2}{1 - h_i} - \frac{1}{2} \ln \frac{s_i^2}{s_i^2} \quad (6.1)
\]

and using the fact that, for \( n \) large,

\[
\ln \frac{s_i^2}{s_i^2} \approx \ln \left( 1 + \frac{t_i^2}{n} \right) \approx \frac{t_i^2}{n} \quad (6.2)
\]

and since when \( n \) is large, \( t_i \approx r_i \), we have that, asymptotically,

\[
M_i(\beta, \sigma^2) \approx \frac{1}{2} \frac{t_i^2}{1 - h_i} - (1 - h_i) \frac{t_i^2}{2} + \frac{1}{2} \frac{h_i^2}{1 - h_i} - \frac{1}{2} \frac{t_i^2}{2n} \quad (6.3)
\]

so that, for \( n \) large,

\[
M_i(\beta, \sigma^2) \approx \frac{1}{2} \frac{h_i}{1 - h_i} \left[ (2 - h_i)t_i^2 + h_i \right] \quad (6.4)
\]

The above shows that \( M_i(\beta, \sigma^2) \) is a linear increasing function of \( t_i^2 \). The slope depends on \( h_i \), and the scale factor is a standard measure of leverage.

In order to discuss the relationship between \( M_i(\beta, \sigma^2) \) to \( c_i \), we put both in the same scale by comparing \( M_i(\beta, \sigma^2) \) to \( \log c_i \). Then

\[
\log c_i = K - \frac{n}{2} \log \frac{s_i^2}{s^2} - \frac{1}{2} \log(1 - h_i) \quad (6.5)
\]

and using (6.2)

\[
\log c_i = K + \frac{t_i^2}{2} - \frac{1}{2} \log(1 - h_i) \quad (6.6)
\]
which shows that log $c_i$ is also a linear increasing function of $t_i^2$. The main difference between (6.4) and (6.6) is the way each of them deals with the leverage. $M_i(\beta, \sigma^2)$ is concerned with both outliers and influential points and the leverage factor $h_i/(1 - h_i)$ is the one that appears naturally in the standard influence measures such as Cook’s statistics. On the other hand, log $c_i$ is a measure of spuriousness and does not include a product term between the outlier measure $t_i^2$ and the leverage measure $(1 - h_i)$.

It is interesting to relate these measures to other statistics suggested in the literature to achieve the same objective. Andrews and Pregibon (1978) proposed the ratio

$$R_i = \left( \frac{n - p - 1}{n - p} \right) \frac{s_{ij}^2}{\sigma^2} (1 - h_i) \quad (6.7)$$

and they identify outliers with the association of small values of this statistic. Belsley, Kuh, and Welsch (1980) suggested a similar statistic based on the volume of confidence ellipsoids. See Cook and Weisberg (1982) and Chatterjee and Hadi (1986) for a comparison of these measures. Now to compare (6.7) with the previous statistics in the same scale we take minus the logarithm of $R_i$ to obtain, for large $n$,

$$-\log R_i = -\log \frac{s_{ij}^2}{\sigma^2} - \log(1 - h_i) \quad (6.8)$$

and if we compare above with (6.5) it is obvious that $c_i$ is taking into account the sample size in the evaluation of the observation point whereas, the Andrews and Pregibon statistic does not.

In summary, $M_i(\beta, \sigma^2)$ and $c_i$ provides us with complementary information about interesting points in the data set. The points identified as interesting by all the above measures could be further analyzed using $M_i(\beta)$ and $M_i(\sigma^2)$ to differentiate between influential observations and outliers.
7. AN ILLUSTRATIVE EXAMPLE - THE MICKEY DUNN CLARK DATA

For this example, we will continue the famous "MDC data set" due to Mickey, Dunn and Clark (1967), and reported on in Cook and Weissberg (1982), Draper and Smith (1981), amongst others. We list the data in Table 7.1., and a plot is given in Figure 7.1.

This data gives \((X, Y)\) values for \(n = 21\) students, where \(X = \) age at first word (months) and \(Y = \) score of Gessell aptitude test. It is assumed that the linear relation \(E(Y|x) = \beta_0 + \beta_1 x\) is appropriate, so that in our notation \(p = 2\).

Table 7.1.

Figure 7.1. A plot of the MDC Data \((n = 21)\)

In the language of Sections 3 and 4, then, we first set \(k\) and compute the resulting \(\binom{n}{k}\) 's, given by (3.1). For the MDC data, we have let \(k = 1, 2, 3\). (That is, bearing in mind that \(.1n = 2.1\) for this set of data, we have set \(k_0 = 3\).) We have entered the largest \(6\) 's in Table 7.2.
Table 7.2.

</tr>
</tbody>
</table>

* The numbers in brackets are the $(i_1, i_2, \ldots, i_k)$ that correspond to the accompanying $c_l$ value.

We see from Table 7.2. that the maximum of the maximum $c_l$'s occurs at $k = 1$ with $c_{19} = \text{Prob}(Y_{19} \text{ is spurious } | k = 1) = .8153$. We note too that for $k = 1$, the second largest $c$ is $c_3$ or $c_{13}$ having value .0180, or put more dramatically, $c_{19}/c_3 = 45.3$. We also note the consistency with which observations $Y_j$, for $j = 19, 3, 13$, get into the act - for $k = 2$, we have $\max c_{i_1, i_2} = c_{12, 19} = c_{3, 19} = .1096$ and for $k = 3$, $\max c_{i_1, i_2, i_3} = c_{3, 12, 19} = .0459$. We note too that for $k = 2$, $c_{19,19}/c_{11,19} = c_{3, 11} = 1.55$, and for $k = 3$, $c_{19,3,13}/c_{19,3,14} = c_{19,3,13}/c_{10,3,14} = 1.87$, and these ratios are pedestrian when compared with $c_{19}/c_{3} = 45.3 = c_{10}/c_{3}(k = 1)$. Thus, even at this stage of the diagnosis, evidence, is building that $k = 1$, and indeed that $Y_{19}$ is the spurious observation.

Using (4.5) and (4.11), we obtain the numerical results of Table 7.3. (Complete listings of values of $c_l$'s $\beta_k$'s and $D_k$'s are available from the authors).

Table 7.3.

The diagonal elements, $V_{ll}$, of the matrices $V(\beta | \text{data}; k)$

<table>
<thead>
<tr>
<th></th>
<th>$k = 0$</th>
<th>$k = 1$</th>
<th>$k = 2$</th>
<th>$k = 3$</th>
</tr>
</thead>
<tbody>
<tr>
<td>$V_{11}(\beta</td>
<td>k)$</td>

<td>20.90559</td>
<td>22.67359</td>
</tr>
<tr>
<td>$V_{22}(\beta</td>
<td>k)$</td>
<td>0.16753</td>
<td>0.08073</td>
<td>0.08954</td>
</tr>
</tbody>
</table>
We note that the diagonal elements $V_{11}$ and $V_{22}$ attain their minimums in both cases at $k = 1$, providing yet more evidence that there seems to be one spurious observation, the observation $Y_{19}$, in this data set. Tentatively, then, we consider the use of $p(\beta|\text{data}; k = 1)$ to do inference re $\beta$ (and/or $p(\sigma^2|\text{data}; k = 1)$ and/or $p(\beta, \sigma^2|\text{data}; k = 1)$, depending on objectives). Indeed, for $p(\beta|\text{data}; k = 1)$ it turns out that

$$E(\beta|\text{data}; k = 1) = \begin{pmatrix} 109.40284 \\ -1.17759 \end{pmatrix}$$

$$V(\beta|\text{data}, k = 1) = \begin{pmatrix} 20.90559 & -1.12645 \\ -1.12645 & 0.08073 \end{pmatrix}.$$

</tbody>
</table>
Now we have calculated $M_i(\beta, \sigma^2)$ of (5.17), and have tabulated the results in Table (7.4). Examination of the values of $M_i(\beta, \sigma^2)$ yields the fact that for this measure, nineteen of the $n = 21$ have value less than or equal to .1853, but $M_{18}(\beta, \sigma^2)$ and $M_{19}(\beta, \sigma^2)$ have values of 1.5157 and 2.8919, respectively, which are 8.18 and 15.61 times larger, respectively then .1853.

![Figure 7.2. A plot of $M_i(\beta, \sigma^2)$ against log $c_i$ [Mickey Dunn Clarke Data, n = 21]]

We have plotted $M_i(\beta, \sigma^2)$ versus log $c_i$ in Figure 7.2. The graph shows that $M_i(\beta, \sigma^2)$'s have the same behaviour in all points except for observation 18. The probability $c_i$ says that this observation is not likely to be spurious, whereas $M_i(\beta, \sigma^2)$ says that the 18th point is either outlying, influential or both.

To help us to differentiate between outlying and influential points, we look at the statistics $M_i(\sigma^2)$ and $M_i(\beta)$. These values are also shown in Table 7.4. $M_i(\sigma^2)$ shows clearly that the only outlying point is observation 19, with value 2.2745 which is 57.58 times greater than the next largest value, 0.0395 attained for observations 3 and 13.
Going to $M_i(\beta)$, we see that the most influential point is observation 18, with a value of 1.5396 that is twice as large as the one for the spuriously generated observation 19, and 9.32 times the next largest.

Table 7.4 also shows the values of $h_i$ and $t_i^2$ for the MDC data. It can be seen that all observations have approximately the same leverage (between .05 and .15) except for observation eighteen that has a leverage of .65. Then, from the results of Section 6, we would expect a linear relationship between $t_i^2$ and $\log c_i$, except for observation 18. Figure 7.3 shows this graphically. The values of $h_i$ and $t_i^2$ are given for completeness in Table 7.4.

Now from the joint distribution of $(\beta_0, \beta_1) = \beta'$, given in (4.7) with $k = \hat{k} = 1$, $n = 21$, $p = 2$, we may find the posterior marginals of either $\beta_0$ or $\beta_1$ using properties of the bivariate $t$-distribution. We now illustrate the case where interest is in $\beta_1$. We
need additional notation - suppose we let the \((2 \times 2)\) matrix

\[
G(i) = \left[ \frac{n - k - p}{S(i)} (X_i'X_i) \right]^{-1},
\]

(7.2)

and denote the 2 - 2 element of \(G(i)\) by \(g_{22}^{(i)}\), and set

\[
\omega_{22}^{(i)} = (g_{22}^{(i)})^{-1}
\]

(7.3)

Then, from properties of the multivariate \(t\)-distribution, and consulting (4.7) with \(p = 2\), \(k = 1\), we have

\[
p(\beta_1|\text{data}; k = 1) = \sum \phi_{h_1(\beta_1|\hat{\beta}_1^{(i)}), \omega_{22}^{(i)}; n - k - p = 18}.
\]

(7.4)

Here, \(\sum\) denotes the sum over all possible sets \(i = \{i_1\} \subset (1, \ldots, n)\), etc. Recall from (7.1) that

\[
E(\beta_1|\text{data}; k = 1) = -1.17759; V(\beta_1|\text{data}, k = 1) = 0.08073
\]

(7.5)

We have tabulated (7.4) and graphed this posterior density in Figure 7.4. The relative smooth (slightly asymmetric) curve is no doubt due to the fact the \(c_{19}\) is so much larger than all the other \(c_i\)'s, so that the curve is dominated by \(c_{19} \times p(\beta_1|y_{19}; k = 1)\). Using our tabulations, we have incorporated these computations into some numerical integration routines and have found posterior HPD intervals for \(\beta_1\) at level \(1 - \alpha = .90, .95, .99,\)
and tabulated these in Table 7.5.

Figure 7.4. The posterior of the slope $\beta_1$ given in (7.4) based on the MDC data set.

Table 7.5.

The $100(1 - \alpha)\%$ posterior HPD limits for $\beta_1$ based on (7.4)

ACKNOWLEDGEMENTS

An extensive and thorough report from an anonymous referee proved to be very stimulating and helpful, and we wish to acknowledge and thank him/her for the report that has led to a much improved and stronger manuscript. Also discussions with Norman Draper and Muni Srivastava have improved the manuscript and are gratefully acknowledged. The authors would like to thank Boon Ping Chew for programming assistance (all programs used are available on request). The authors’ research was supported by various grants - I. Guttman by NSERC (Canada) under Grant No. A8743, while D. Peña by DGICYT (Spain), under Grant No. PB90-0266.
